Alpha$_2$-adrenoceptor agonists, such as clonidine, are used to treat hypertension and migraine. Clonidine lowers blood pressure by inhibiting the release of norepinephrine from sympathetic nerves, an effect mediated by presynaptic α_2-

adrenoceptors, and by acting on centres in the brain that are concerned with the control of blood pressure. It is a potent and effective drug, but it has the disadvantage that the blood pressure may rise to a dangerously high level if the drug is stopped or even if the patient misses a dose. The basis for its antimigraine effect is not understood.

Beta$_2$-adrenoceptor agonists relax smooth muscle in many parts of the body (see below *Drugs affecting muscle: smooth muscle*) and are used mainly to treat asthma and other allergic disorders. None of the available drugs is completely selective for the β_2-adrenoceptor, and they tend to produce unwanted effects on the heart, such as increased heart rate and disturbances of cardiac rhythm, through their action on cardiac β_1-adrenoceptors.

Step 5. The action of the released norepinephrine is terminated when it is recaptured by sympathetic nerve terminals, a process that involves a selective transport mechanism in the neuronal membrane. Various drugs block this transport system and thus enhance the effects of sympathetic nerve activity; the most important examples are cocaine and certain antidepressant drugs such as imipramine. Overdosage with these drugs results in overactivity of the sympathetic system and the occurrence of cardiac dysrhythmias. The effects of these drugs on brain function, which are of more clinical importance than their peripheral sympathomimetic effects, may be due to this action of inhibiting the uptake of norepinephrine into adrenergic neurons in the brain. (H.P.R.)

CENTRAL NERVOUS SYSTEM PHARMACOLOGY

Anesthetics. Anesthetics are drugs that induce a temporary inability to perceive any sensory stimuli by acting on the brain or peripheral nervous system to suppress responses to sensory stimulation, primarily to touch, pressure, and pain. Such drugs permit the humane application of medical or dental surgical procedures. Anesthesia is the unresponsive state induced by anesthetic drugs. General anesthetics induce anesthesia throughout the body and can be administered either by inhalation or by direct injection into the bloodstream. Local anesthetics provide restricted anesthesia with full retention of consciousness and internal neuronal regulation and are applied to the peripheral sensory nerves innervating a region.

General anesthetics. Inhaled anesthetics act very quickly because of their rapid access into the bloodstream of the lungs and from there directly into the arterial circulation to the brain. The relationship between the amount of general anesthetic administered and the depression of the brain's sensory responsiveness is arbitrarily, but usefully, divided into four stages. Stage I is the loss of consciousness, with modest muscular relaxation, and is suitable for short, minor procedures. Additional anesthetic induces stage II, in which increased excitability and involuntary activity makes surgery impossible; rapid passage through stage II is generally sought by physicians. Full surgical anesthesia is achieved in stage III, which is further subdivided on the basis of the depth and rhythm of spontaneous respiration, pupil reflexes, and spontaneous eye movements. Stage IV anesthesia is indicated by the loss of spontaneous respiration and the imminent collapse of cardiovascular control.

Stages of anesthesia

Not infrequently, general anesthetics are combined with drugs that block neuromuscular impulse transmission. These additional drugs are given to relax muscles in order to make surgical manipulations easier with less suppression of brain activity. Under these conditions, artificial respiration may be required to maintain proper levels of oxygen and carbon dioxide in the blood. The ideal anesthetic agent allows rapid and pleasant induction (the process that brings about anesthesia), close control of the level of anesthesia and rapid reversibility, good muscle relaxation, and few toxic or adverse effects. Some anesthetics have been rejected for therapeutic use because they form explosive mixtures with air, because of their excessive irritant action on the cells that line the major bronchioles of the lung, or because of their adverse effects on the liver or other organ systems.

General anesthesia can be produced by a wide range of chemicals, and most can be administered by inhalation in mixtures with oxygen, permitting the gases to mix with the arterial blood on penetration through the walls of the alveoli within the lung. Rapid induction requires a potent anesthetic with molecular properties that permit efficient transfer between alveolar air spaces and the pulmonary circulation. This rapid route of administration also permits the rapid washout of blood levels of the anesthetic when oxygen alone is administered. Most inhalation anesthetics are excreted by the lungs with little or no metabolism by the body. Safe anesthesia with general anesthetics, such as the intravenously injected barbiturates, requires very short-acting compounds so that the anesthetist can maintain control over the depth of anesthesia while the drug is excreted by the kidney or metabolized by the liver. The mechanism of action of inhalation anesthetics is not well understood.

Except for the naturally occurring gas nitrous oxide, all of the currently used major inhalational anesthetics are hydrocarbons, which are compounds formed of carbon and hydrogen atoms. Each carbon has the potential to bind four hydrogen atoms. The potency of a given series of hydrocarbons depends on the nature of the bonds between the carbons and the degree to which the hydrogen atoms have been replaced with halogens. In the ethers, the carbon atoms are connected through a single oxygen, as in diethyl ether, and again halogen substitution increases potency, as is seen in enflurane, fluroxene, and methoxyflurane. A peculiar, unpredictable, and serious adverse property of halogen anesthetics is their ability to trigger a hypermetabolic reaction in the skeletal muscles of certain susceptible individuals. This potentially fatal response, termed malignant hyperpyrexia, produces a very rapid rise in body temperature, oxygen utilization, and carbon dioxide production.

Nature of most inhalational anesthetics

Rapid, safe, and well-controlled anesthesia can be obtained by the intravenous administration of certain rapidly acting depressants of the central nervous system, such as the barbiturates, the benzodiazepines, or certain synthetic opiates. These systemic anesthetics can be used to produce rapid induction without the discomfort that may accompany induction with the gaseous anesthetics, which are then used to maintain anesthesia. Although opiates such as fentanyl can be used to induce anesthesia, their use is generally limited to very short procedures. Primary advantages are the stability of the cardiovascular system in the presence of this drug and the ability to reverse the effects rapidly with the antagonist drug maloxone. Neither the barbiturates nor the benzodiazepines have any analgesic potency, and barbiturates may, in fact, enhance postsurgical sensitivity to pain. (F.E.Bl.)

Local anesthetics. Local anesthetics produce a loss of sensation in a specific area as a result of their administration into a restricted region, usually by injection. Thus, local anesthetics are useful in minor surgical procedures, such as the extraction of teeth. The first known and generally used local anesthetic was cocaine, an alkaloid extracted from coca leaves obtained from various species of *Erythroxylon.* In the 1880s cocaine was first introduced to the field of ophthalmology for anesthetizing the cornea; later it was used in dental procedures.

The feeling of pain depends upon the transmission of information from a traumatized region to higher centres in the brain. The information is passed along fine nerve (sensory) fibres from the peripheral areas of the body to the spinal cord and then to the brain. If these pain fibres are sectioned, pain sensations from their origins in the periphery are lost. Local anesthetics cause a temporary blocking of conduction along these nerve fibres, producing a temporary loss of pain sensation.

Transmission along nerve fibres

Local anesthetics can block conduction of nerve impulses along all types of nerve fibres, including motor nerve fibres that carry impulses from the brain to the periphery. It is a common experience with normal dosages of an anesthetic, however, that while pain sensation may be lost, motor function is not impaired. For example, use of a local anesthetic in a dental procedure does not prevent movement of the jaw. The selective ability of local anesthetics to block conduction depends on the diameter of the nerve fibres and the length of the fibre that must be affected to block conduction. In general, thinner fibres are

blocked first, and conduction can be blocked when only a short length of fibre is inactivated. Fortunately, the fibres conveying the sensation of dull aching pain are among the thinnest, and the most susceptible to local anesthetics. If large amounts of local anesthetic are used, pain is the first sensation to disappear, followed by sensations of cold, warmth, touch, and deep pressure.

There are many synthetic local anesthetics available, such as procaine, lidocaine, and tetracaine. It is the convention to end the names of local anesthetics with "-caine," after cocaine, which was the first local anesthetic known. In general they are secondary or tertiary amines linked to aromatic groups by an ester or amide linkage. Thus one end of the molecule is hydrophilic ("water loving") while the other end is hydrophobic ("water hating"). The hydrophobic nature of the molecules make it possible for them to penetrate the fatty membrane of the nerve fibres and exert their effects from the inside. When an impulse passes along a nerve, there are transient changes in the properties of the membrane that allow small electrical currents to flow. These currents are carried by ions, especially sodium ions. The influx of these sodium ions through small channels that open briefly in the surface of the nerve membrane during excitation transports the impulse. Local anesthetics block these channels from the inside, preventing the movement of the sodium ions and small electrical currents. The action of a local anesthetic is terminated as the agent is dispersed, metabolized, and excreted by the body. Its dispersal from the injection site depends, in part, on the blood flow through the region. Cocaine, for example, causes blood vessels to constrict, reducing the dispersal rate; other local anesthetics do not have this effect.

Local anesthetics are used to induce limited areas of anesthesia. The limited area is achieved largely by the site and method of administration and partly by the physiochemical properties of the drug molecules. The drug may be injected subcutaneously around sensory nerve endings, enabling minor operations such as tooth extraction to be performed. This is called infiltration anesthesia. Some local anesthetics are applied directly to mucous membranes, such as those of the conjunctiva of the eye or those of the nose, throat, larynx, or urethra. This is called surface or topical anesthesia. A familiar example of topical anesthesia is the use of certain local anesthetics in throat lozenges to relieve the pain of a sore throat. Local anesthetics may be injected near a main nerve trunk in a limb to produce what is called conduction or regional nerve block anesthesia. In this situation, conduction in both motor and sensory fibres is blocked, enabling operations to be carried out on a limb while the patient remains conscious. A special form of regional nerve block may be achieved by injecting a local anesthetic into the spinal canal, either into the space between the two membranes (the durae) that surround the cord (epidural anesthesia) or into the cerebrospinal fluid (spinal or intrathecal anesthesia). In spinal anesthesia, the specific gravity of the local anesthetic solution is appropriately adjusted and the patient is tilted in such a way that the anesthesia is confined to a particular region of the spinal cord. In both epidural and spinal anesthesias, the anesthetic blocks conduction in nerves entering and leaving the cord at the desired level. (A.W.C.)

Infiltration and surface anesthesia

Analgesics and narcotics. Analgesics are drugs that relieve pain selectively without affecting consciousness or sensory perception. This selectivity in relieving pain is the important distinction between an analgesic and an anesthetic. Analgesics are often self-prescribed and abused. Many strong analgesics can produce serious and even fatal depression of the central nervous system. Furthermore, the use of analgesics can involve such problems as addiction, fatal overdose, allergic reaction, and significant gastrointestinal irritation. Analgesics may be classified into two types: the opioids, which act on the brain; and anti-inflammatory drugs, which alleviate pain by reducing local inflammatory responses.

The opioid analgesics were once called narcotic drugs because they induce sleep and cause dependence or addiction. This term is no longer used by physicians or scientists since both dependence and addiction can be induced by many drugs other than opioids. The opioid analgesics can be used for either short-term or long-term relief of severe pain. In contrast, the anti-inflammatory compounds are non-narcotic analgesics and are used for short-term pain relief and for modest pain, such as that of headache, muscle strain, bruises, or arthritis.

Anti-inflammatory analgesics. Several chemically unrelated series of complex organic acids have the ability to relieve mild to moderate pain through actions that reduce inflammation at its source. The prototype of this class of drugs is acetylsalicylic acid, or aspirin. Like aspirin, many of the drugs of this class also reduce fever (antipyretic action), and those that resemble aspirin most closely share what is presumed to be its molecular mechanism of action, namely inhibition of the synthesis of prostaglandins (natural products of inflamed leukocytes, which induce the responses in local tissue that include pain and inflammation). These three properties of anti-inflammatory drugs (*i.e.*, analgesia, anti-inflammation, and antipyretic action) vary among the drugs.

Aspirin

Aspirin, which is now made by total chemical synthesis, is the most widely used mild analgesic, although more potent antipyretic analgesics, such as acetaminophen, are available. Super-aspirins, such as indomethacin, were developed in the 1970s as the mechanisms of critical analgesic actions, namely prostaglandin synthesis inhibition, came to be understood.

Research has shown that small doses of certain prostaglandins can mimic almost all of the signs and symptoms of localized inflammation. Prostaglandins are naturally occurring by-products of arachidonic acid synthesis. They are thought to be released at the site of inflammation when leukocytes are attracted to injured or inflamed areas. All mammalian cells except red blood cells can produce prostaglandins, and when injured, the cells release large amounts of these substances. All aspirin-like analgesics inhibit prostaglandin synthesis and release, and their varying potencies depend on the degree to which they can do so.

As might be expected from their common mechanisms of action, many of the non-narcotic analgesic drugs share similar side effects. Hypersensitivity responses to aspirin-like drugs are thought to be due to an accumulation of prostaglandins after the pathways that break down prostaglandins are blocked. These responses can be fatal when very strong anti-inflammatory compounds are given. Inhibition of prostaglandin synthesis may result in other serious side effects, such as gastric ulcers (which may also be due in part to the irritant activity of large doses of aspirin on the lining of the stomach) and the reduced ability of platelets in the blood to aggregate and form clots. The latter effect, however, has given aspirin an added use as a prophylactic antithrombotic drug to reduce chances of cardiac or cerebral vascular thrombosis. Some of these aspirin-like analgesics also have specific toxic effects: liver damage occasionally occurs after administration of acetaminophen, and renal toxicity and behavioral symptoms are sometimes seen with use of the super-aspirin anti-inflammatory drugs. Aspirin is thought to be a causative agent of Reye's syndrome, a rare and serious degenerative disease of the brain and fatty tissue of the liver that accompanies certain viral infections in children and young adults.

Treatment of mild pain

For treatment of mild pain, two types of analgesics can be used as alternatives to aspirin. The first type comprises the para-aminophenol derivatives such as acetaminophen, which is not a particularly useful anti-inflammatory drug. The term nonsteroidal anti-inflammatory agent is generally reserved for the second type of aspirin-like analgesic, the newer class of highly potent compounds sometimes termed super-aspirins. These drugs all inhibit prostaglandin synthesis. The first of this series, indomethacin, has been largely discarded because of side effects. The most widely used of the super-aspirins are the proprionic acid derivatives, such as ibuprofen, naproxen, and fenoprofen. Although these drugs are widely tolerated and can give significant analgesia in moderate doses, they have also been shown to cause all of the side effects of the other inhibitors of prostaglandin synthesis.

Opioid analgesics. The term opioid has been adopted as a general classification of all of those agents that share chemical structures, sites, and mechanisms of action with the endogenous opioid agonists. Opioid substances encompass all of the natural and synthetic chemical compounds closely related to morphine, whether they act as agonists or antagonists. Although interest in these drugs has always been high because of their value in pain relief and because of problems of abuse and addiction, interest was intensified in the 1970s and 1980s by discoveries about the naturally occurring morphine-like substances, the endogenous opioid neuropeptides.

Opium is the powder from the dried juice of the poppy *Papaver somniferum*. When taken orally, opium produces sleep and induces a state of peaceful well-being. Its use dates back at least to Babylonian civilization. In the early 19th century opium extract was found to contain more than 20 distinct complex organic bases, termed alkaloids, of which morphine, codeine, and papaverine are the most important. These pure alkaloids replaced crude opium extracts in therapeutics.

In the 1950s several new morphine-like drugs were suggested. Despite the increase in the number of compounds available for pain relief, however, little was understood of their sites and mechanisms of action. The first real breakthrough came from the discovery, by J.W. Hughes and H.W. Kosterlitz, of two potent naturally occurring analgesic pentapeptides (peptides containing five linked amino acids) in extracts of pig brain. They called these compounds enkephalins, and since then at least six more have been found. Larger peptides, called endorphins, have been isolated; and these contain sequences of amino acids that can be split off as enkephalins. There are at least three types of receptors on brain neurons that are activated by the enkephalins. Morphine and its congeners are thought to exert their effects by activating one or more of these receptors. This is still a rapidly advancing field of research. It is thought that the common final pathway of receptor activation is the movement of calcium ions through the plasma membrane.

Enkephalins

Opioid drugs are useful in the treatment of general postoperative pain, severe pain, and other specific conditions. The use of opiates to relieve the pain associated with kidney stones or gallstones presumably depends on their ability to affect opiate receptors in these tissues and to inhibit contractility. By a similar mechanism, opiates are also able to relieve the abdominal distress and fluid loss of diarrhea. Central receptors appear to account for the ability of morphine and analogues to suppress coughing, an effect that requires lower doses than those needed for analgesia. Low doses of opiates given subcutaneously are also specifically advocated for the relief of the respiratory distress that accompanies acute cardiac insufficiency complicated by the buildup of fluid in the lungs, even though the mechanisms of this effect are unknown and despite the fact that opiates are respiratory depressants.

Several commonly used natural or synthetic derivatives of morphine are used in drug therapeutics. Codeine, a naturally occurring opium alkaloid, is also made synthetically and provides a useful adjuvant analgesia as an oral preparation, especially when used in combination with aspirin. Meperidine, also known as Demerol, was one of the earlier synthetic analogues of morphine that was originally thought to be able to provide significant short-lasting analgesia and little or no addiction because of its shortened duration of action. This belief proved false and the drug is widely abused. Methadone, a synthetic opioid analgesic, has long-lasting (six to eight hours) analgesic effects when taken orally and the unique ability to antagonize the euphoria-producing effects of heroin; it is therefore used to moderate the effects of withdrawal from opiate addiction. Among the opioid antagonist drugs, naloxone and its longer lasting orally active version, naltrexone, are used primarily to reverse morphine overdoses and to reverse the chemical stupor of a wider variety of causes, including alcohol intoxication and anesthesia. In opiate overdoses, where the signs of pinpoint pupils, depressed respiration, and unconsciousness help in the diagnosis, these drugs provide an almost miraculous recovery within minutes of injection. They can, however, also precipitate severe withdrawal reactions if the subject had been addicted previously.

Methadone

The effectiveness of a given dose of an opiate drug declines with its repeated administration in the presence of intense pain. This loss in effectiveness is termed tolerance. Evidence suggests that tolerance is not due to alterations in the brain's responses to drugs. Animals exhibiting tolerance to morphine after repeated injections in a familiar environment show little or no tolerance when given the same doses and tested for pain sensitivity in new environments. Thus, a learned aspect of tolerance seems almost certain. The cellular and molecular mechanisms underlying this loss of responsiveness are not clear, however. Physical dependence and addiction in a person using intravenous administration closely follow the dynamics of drug tolerance; increasing doses are required to produce the psychological effects, while tolerance protects the brain against the respiratory depressant actions of the drug. In the tolerant individual, intense adverse reactions can be precipitated by administration of an opiate antagonist, thus revealing the dynamic internal equilibrium that previously appeared to neutralize the response of the brain to the opiates. The signs of the withdrawal response (yawning, tearing, perspiration, dilation of the pupils, nasal discharge, anxiety, tremors, elevation of blood pressure, abdominal cramps, and hyperthemia) can be viewed as signs of an activated sympathetic nervous system and to some extent an extreme, but nonspecific, arousal response. This may also suggest that tolerance in the face of increasing opiate doses is more properly viewed as a balancing mechanism by this sympathetic activation.

Drugs affecting mood and behaviour. Behaviour and emotions are higher functional properties of the brain that depend on the network of neurons and chemical neurotransmitters that exist throughout the body; however, the means by which neurons achieve changes in behaviour and in mood remains unknown. Nevertheless, certain neurotransmitters, such as the monoamines, norepinephrine, dopamine, epinephrine, serotonin, and acetylcholine, appear to be closely linked to these aspects of brain function. Drugs that influence the operation of these neurotransmitter systems can profoundly influence and alter the behaviour of patients with psychiatric problems.

Drugs that affect mood and behaviour can be classified as follows: antianxiety agents, antidepressants, antipsychotics, antimanics, stimulants, antiappetitives, and antiemetics. Such drugs should be reserved for severe disruptions of normal emotional well-being and should not be used to relieve the boredom, tension, or sadness that may be properly regarded as a normal part of life. Sedative-hypnotics, which depress conscious awareness and induce sleep, are described in a separate section (see below *Sedative-hypnotic drugs*).

Classification

Antianxiety drugs. Anxiety is a state of pervasive apprehension that may be triggered by specific environmental or personal factors. Anxiety states are generally combined with emotions such as fear, anger, or depression. A person suffering from anxiety may complain of physical symptoms such as palpitations, nausea, dizziness, headaches, and chest pains, as well as sleeplessness and fatigue. When such apprehension is severe and incapacitating, the person is said to suffer from anxiety neurosis, which may require treatment by psychotherapy. Many of the drugs used in the treatment of anxiety are for the most part safe and well tolerated and physicians often prescribe them either as an aid to coping with different situations in mild cases.

After World War II Swiss pharmacologists discovered muscle relaxant properties in a compound under investigation as an antibiotic. Modification of that compound led to the tranquilizing drug meprobamate. Another discovery showed that the benzodiazepines, which are complex ringed compounds, had even greater relaxing properties. Hundreds of analogues of the basic benzodiazepine ring were subsequently synthesized. The most widely prescribed compounds, chlordiazepoxide and diazepam, are now giving way to shorter acting compounds that are less likely to produce sedation. Different formulations of the basic

benzodiazepine structure in higher dosages are used as muscle relaxants, antiepileptics, and hypnotics (see below *Sedative-hypnotic drugs* and *Antiepileptic drugs*).

The brain exhibits highly specific, high-affinity binding sites that can selectively recognize, or bind, the benzodiazepine compounds. The cellular and subcellular locations of these sites are near ion channels in the membrane that can admit chloride ions into the cell and also near sites where a neurotransmitter, gamma-aminobutyric acid (GABA), acts. Benzodiazepine agonists in general enhance the effects of GABA. In 1985 scientists in the United States showed that brain extracts contain an endogenous inhibitor of benzodiazepine binding. Assessment of its behavioral effects on the brain suggests that this natural compound may cause rather than suppress anxiety and decrease rather than increase GABA transmission.

Acute treatment with benzodiazepines generally begins with doses taken before bedtime to facilitate sleep. Because the need for the drugs depends on the patient's response to psychotherapy and his ability to reshape the events that lead to the anxiety, more or less tolerance may develop to the sedation. There are side effects with the use of benzodiazepines. Because of the alterations in the effectiveness of inhibitory transmitter actions of GABA, which are profound in the cerebellum and cerebral cortex, the patient may also exhibit confusion and loss of motor coordination. Other drugs, especially alcohol, taken with benzodiazepines can interfere with coordination, and use of these drugs during pregnancy may increase chances of fetal malformations.

Side effects of benzodiazepines

Antidepressants. Clinical depression is characterized by a sad or hopeless mood, a loss of interest in one's usual activities, reduced energy, change of appetite, disturbed sleep patterns, and often contemplation of suicide. An individual must experience these symptoms for at least two weeks in order to be diagnosed with clinical depression. The disorder also must be distinguished from grief felt in reaction to the death of a loved one or some other unfortunate circumstance.

In 1957 imipramine emerged as the first therapeutically useful antidepressant. An accidental discovery led to the finding that the drug iproniazid caused some patients to become extremely euphoric and hyperactive by inhibiting monoamine oxidase, a brain enzyme that normally breaks down norepinephrine and other neurotransmitters. Drugs that were better at blocking the activity of this enzyme were even more effective in evoking euphoria. Shortly thereafter, the monoamine oxidase inhibitors (MAOIs), as they were later called, were introduced for the treatment of depression. Another class of antidepressants called tricyclics, named for their basic three-carbon ring structure, were discovered around the same time as the MAOIs. Tricyclics inhibit the active reuptake of the neurotransmitters norepinephrine, serotonin, and dopamine in the brain. Inhibition of reuptake allows the neurotransmitters to remain in contact longer with their postsynaptic receptors. This mechanism seems to support the hypothesis that depression is caused by a chemical imbalance in the levels of neurotransmitters.

The most common antidepressants used today are selective serotonin reuptake inhibitors (SSRIs). By inhibiting only the reabsorption of serotonin, SSRIs have fewer, less serious side effects than the other classes of antidepressants, which interfere with several neurotransmitter systems and may result in increased sensitivity of the sympathetic nervous system and cardiovascular irregularities. Introduced in the late 1980s, SSRIs include fluoxetine (Prozac), paroxetine (Paxil), and sertraline (Zoloft). Other antidepressants such as buproprion (Wellbutrin) that are chemically unrelated to the other antidepressants also were introduced. Antidepressants are also prescribed for the treatment of obsessive-compulsive disorder, panic disorder, and bulimia nervosa.

Side effects vary among the types of antidepressants and may include sleepiness, tremors, anxiety, loss of sexual desire, and nausea. Although some improvement in symptoms may occur in the first week or two, antidepressant medications typically need to be taken for at least three weeks before the full therapeutic effect of the drug occurs. Most physicians recommend that patients continue to take antidepressants for at least six months to prevent a recurrence of symptoms.

Antimanics. Mania is a severe form of emotional disturbance in which the patient is progressively and inappropriately euphoric and simultaneously hyperactive in speech and locomotor behaviour. This is often accompanied by significant insomnia, excessive talking, extreme confidence, and increased appetite. As the episode builds the patient exhibits racing thoughts, extreme agitation, and incoherence, frequently replaced with delusions, hallucinations, and paranoid fears. Ultimately the patient may become hostile and violent, and may finally collapse. In some patients, periods of depression and mania alternate, giving rise to the form of affective psychosis known as bipolar depression, or manic-depressive disorder. The most effective medications for this form of emotional disorder are the simple salts lithium chloride or lithium carbonate. Although some serious side effects can occur with large doses of lithium, the ability to monitor blood levels and keep the doses within modest ranges (approximately one milliequivalent [mEq] per litre) makes it an effective remedy for manic episodes and it can also stabilize the mood swings of the manic-depressive patient.

Lithium salts

In the 1940s lithium salts were used briefly as a possible sodium substitute for subjects with cardiac failure and hypertension until the salts' serious effects on cardiac rhythms became apparent. The use of lithium in the treatment of mania emerged from a series of ambiguous and ill-conceived observations. Lithium was given to manic patients who showed the calming effects now recognized as valid therapeutic responses. The treatment was initially regarded skeptically, and its use was long delayed in the United States. Lithium is now an accepted and preferred form of long-term treatment for both manic and manic-depressive patients.

Given the simplicity of the salt, the fact that therapeutic action resides in lithium itself and not the anion that accompanies it, and that there is no direct metabolism of the lithium, scientists have been unable to determine how the antimanic effects arise. The use of lithium involves a latent period of 10–14 days before the mania subsides, after which, if blood lithium levels are kept constant (within the one mEq plasma concentration), there is generally a good stabilization of the patient's moods. The positively charged lithium ions enter into a biophysical equilibrium with calcium and magnesium, and this replacement action, with slow accumulation in the cells of the brain, is regarded as critical for the stabilization of emotion.

If patients take an overdose, or if their normal salt and water metabolism becomes unbalanced by intervening infections that cause anorexia or fluid loss, then signs of lithium overdose may become apparent. Such signs include loss of coordination, drowsiness, weakness, slurred speech, and blurred vision, as well as more serious chaotic cardiac rhythm and brain-wave activity with seizures. Because lithium is generally excreted along with sodium in the urine, rehydration and supportive therapy are all that are required. Prolonged treatments with lithium, however, can in fact damage the body's ability to respond properly to the antidiuretic hormone, which stimulates the reabsorption of water, thus causing the emergence of diabetes insipidus. Lithium can also interfere with the response of the thyroid gland to the thyroxin-stimulating hormone produced in the pituitary gland. Both the renal and thyroid effects of lithium have been attributed to the blockade of a cell surface response that requires the target cell to synthesize the intracellular mediator cyclic adenosine monophosphate.

Antipsychotic drugs. The severe form of mental illness known as schizophrenia is usually a chronic, often lifelong, inability to think logically and act appropriately. Effective treatments for some forms of schizophrenia have revolutionized thinking about the disease and have prompted investigations into its possible genetic origins and biopathological causes. Of the three most common patterns of schizophrenic psychosis, treatments with antipsychotics are the most useful in the case of young adults who show an acute onset of paranoid fears and halluci-

Treatment of schizophrenia

nations and in middle-aged adults whose childhood and adolescence were marked by poor interpersonal relationships and disturbed thinking.

Each of the three major series of drugs that have been used successfully in the treatment of schizophrenia has a colourful origin. The history of reserpine can be traced to the Indian shrub called *Rauwolfia serpentina* for its snakelike appearance, which historically had been used to treat snake bites, insomnia, high blood pressure, and insanity. Reserpine, the principle alkaloid of the plant, was first isolated in the 1950s and used in the treatment of hypertension; it was later given to disturbed schizophrenics, in whom the drug was found to act as a behavioral depressant. In fact, the depression of patients given the drug for hypertension was a major side effect. The basic mechanisms of action of reserpine in producing depression are attributed to its ability to deplete the brain's stores of the monoamines.

The second major class of antipsychotic drugs, the phenothiazines, arose from modifications of the dye methylene blue, which was under investigation as an antagonist of histamine. Attempts to modify this series to increase their activity in the central nervous system and reduce the need for surgical anesthetics ultimately led to the first effective drug of this class, chlorpromazine. Its ability to stabilize behaviour and to improve lucidity as well as to reduce hallucinatory behaviour was recognized throughout the world within a few years of its introduction. The use of chlorpromazine changed the role of the mental hospital and resulted in the large-scale, perhaps excessive, discharge of medicated schizophrenics into the outside world.

The third class of antipsychotics, the butyrophenones, emerged when a small Belgian drug company embarked on an ill-conceived plan to develop analogues of Demerol (a synthetic narcotic analgesic) through cheap chemical substitutions. Experiments gave rise to a compound that caused chlorpromazine-like sedation but had a completely different structure. This led to the compound haloperidol, a more powerful antipsychotic with relatively fewer side effects.

Drugs related to chlorpromazine and to haloperidol share several actions in humans and in animals. These drugs are sedatives, which means that they can suppress the vomiting reflex and nausea (for this reason they are used in the early stages of pregnancy), and they can improve many of the symptoms of schizophrenia in a significant number of patients. Although its mechanisms of action are not well established, they are thought to involve a deficiency of the monoamine transmitter dopamine. Schizophrenia may be brought about either by an excessive release of dopamine or, more likely, by increased sensitivity to dopamine. Thus the effectiveness of the antipsychotic drugs chlorpromazine and haloperidol, as well as chemically related drugs, may be attributed to their ability to antagonize, or inhibit, the actions of dopamine.

Side effects of chlorpromazine and haloperidol

The major acute side effects of chlorpromazine and haloperidol are oversedation and a malaise that makes the drugs poorly received by the patient and makes compliance with chronic self-medication difficult. On prolonged treatment of middle-aged and even young adults, antipsychotic drugs can evoke serious movement disorders that in part resemble Parkinson's disease, a degenerative condition of the nerves. First to appear are tremors and rigidity, followed by more complex movement disorders commonly associated with involuntary twitching movements on the arms, lips, and tongue, called tardive dyskinesia. The latter disorder also has been described in nonpsychotic subjects who were sedated and in untreated schizophrenic patients. One explanation for this side effect is that these movement disorders may be a part of the natural course of the psychotic disease but can be greatly exacerbated by treatment with the dopamine antagonist drugs. In addition to these often irreversible side effects, there can also be adverse liver, cardiac, and bone marrow toxicity. Because of these problems with long-term treatment and because most schizophrenic patients are helped minimally if at all, the search for the other possible causes of the psychosis and of other forms of antipsychotic therapy has continued.

Sedative-hypnotic drugs. Drugs that reduce tension and calm anxiety at low doses (see above *Antianxiety drugs*) and that produce drowsiness and facilitate the onset of sleep at higher doses are called sedative-hypnotics. Because this state of sleep is one from which a patient can normally be aroused, its production was once attributed to "hypnotic" actions, but the sleep that is induced is actually quite natural. Still higher doses of some sedative-hypnotics can produce deep unconsciousness sufficient to make them useful as general anesthetics.

The dose levels at which calm, sleep, or anesthesia are induced depend on the drug classes and their mechanisms of action. Since similar effects can be obtained with other drugs, such as analgesic opiates or antianxiety benzodiazepines, the principal characteristic of primary sedative-hypnotics is their selective ability to induce these actions without affecting mood or sensitivity to pain.

Alcoholic beverages and alcoholic extracts of opium were traditionally used as sedative-hypnotics, but the first substance introduced specifically as a sedative and as a hypnotic was a liquid solution of bromide salts. In 1869 chloral hydrate became the first synthetic organic molecule to be employed specifically for its sedative-hypnotic effect, and it was followed by several others, notably paraldehyde. (Chloral hydrate was used notoriously as "knock-out" drops.) Barbiturates, with their more complex organic ring structure, were introduced in the early 1900s, and hundreds of barbiturate analogues were then synthesized with varying potencies and durations of action. Potent analogues of barbiturates have been used to induce surgical anesthesia and to reduce voluntary inhibition during psychiatric interviews (for which they have sometimes been dubbed "truth serums"). Most of the barbiturates were discontinued after the development in the 1950s of the benzodiazepines, many of which exhibit the ideal properties of a short-acting, intense facilitator of natural sleep, with a reduced risk of adverse effects.

Depressant effects of alcohol

The means by which alcohol depresses brain function and produces sleep is not clear; however, it is certain that intoxicating doses of alcohol greatly incapacitate the processing of information, reduce reaction times, and depress skilled locomotor behaviours. No single neurotransmitter system has been definitively shown to be the locus of these behavioral effects, and multiple mechanisms may be involved. Barbiturates and benzodiazepines have similar but not identical actions at the behavioral and cellular level to those of alcohol. The benzodiazepines act on the inhibitory sites at which gamma-aminobutyric acid (GABA) is the neurotransmitter.

Effects of alcohol and barbiturates

In certain persons low doses of alcohol, barbiturates, and some benzodiazepines produce transiently enhanced mood or euphoria, along with antianxiety effects. These behavioral effects can lead to abuse of these substances and to dependence upon them with prolonged use. High doses can depress critical centres in the brain stem for the regulation of cardiovascular and respiratory function.

When sedatives are taken frequently as sleeping tablets, tolerance and a reduction in effectiveness occurs. Despite popular beliefs to the contrary, alcoholic beverages in particular are only of modest benefit to induce sleep. On frequent exposure to alcohol the nervous system adapts to the drug, and this results in early morning awakening. Barbiturates can be selected to provide both early onset of sleep and a prolongation of sleep. Analysis of electroencephalographic patterns during barbiturate-induced sleep, however, shows that there is more disruption of sleep. There have been reports that some benzodiazepines used as sleep inducers produce less disruption of the sleep phases, a property that makes them especially useful for persons with sleep disturbances.

Antiepileptic drugs. Epilepsy is a general term for a group of central nervous system disorders characterized by transient but repeated episodes of abnormal electroencephalographic activity that correlate with abnormal motor behaviour (convulsions) and, less commonly, with sensory, autonomic, or psychological manifestations. Although some forms of epilepsy may be caused by high fevers, especially in infants, and while some forms of epilepsy in adults can be traced to previous brain injury, with resulting scars, or to brain tumours, the causes of

Treatment of epilepsy

most forms are unknown. As a result of the uncertain origin, the treatment of epilepsy is directed toward reducing the frequency of seizure. Moreover, many of the drugs that have been found to be useful have led to trial-and-error testing of analogues of barbiturate and benzodiazepine sedatives. An accurate diagnosis of the form of epilepsy is critical to the drug most likely to be effective.

The mechanism of action of most antiepileptic drugs is unknown, except for the barbiturates and the benzodiazepines, which act by enhancing the effectiveness of the inhibitory neurotransmitter substance GABA. Other drugs were discovered by testing their ability to prevent seizures in experimental animals after electrical stimulation of the brain or after the administration of convulsant drugs such as strychnine, pentylenetetrazol, or metrazol. On the other hand, the hydantoins, such as phenytoin, were discovered as a result of persistent testing of a series of drugs. Phenytoin is effective in the long-term treatment of many varieties of epilepsy, especially in combination with more sedative barbiturates.

The tricyclic antidepressant drug carbamazepine, used in the treatment of trigeminal neuralgia, was later found to have value in the treatment of epileptic disorders. It is also effective against some chemically induced seizures. The effectiveness of the drug has been attributed to its ability to enhance monoaminergic transmission.

Because most epileptic conditions are long-lasting and of unknown origin, their treatment is confined to drugs. As might be expected, side effects after prolonged use are common. Phenytoin, for example, may be directly toxic to neurons of the cerebellum, and this may actually exacerbate the seizures. In addition, this drug can cause gingival hyperplasia and hirsutism, which may lead patients to abandon it.

Anti-Parkinson drugs. Parkinson's disease, or paralysis agitans, is a severe progressive degenerative disease of the nerves characterized by tremor of the distal limbs that disappears when movement is initiated. Later in the course of the disease the muscles become rigid, and the initiation of movements and their termination, once started, become so difficult as to be incapacitating. In the final stages the patient is unable to maintain an erect posture, speak, write, or focus the eyes. Although the loss of pigmented neurons of the brain region called the substantia nigra had been a pathological finding in postmortem specimens since the early 20th century, a pathophysiological explanation of the disorder was not found until 1960. These neurons use the substance dopamine as their neurotransmitter, and they project onto the basal ganglia, a centre for the coordination of movement. Patients with Parkinson's disease were found to have basal ganglia greatly deficient in dopamine.

Debilitating course of Parkinson's disease

Recognition that this chemical deficiency of a specific neurotransmitter was a central feature of the disease led to a new therapy based on the use of the amino acid L-3,4-dihydroxyphenylalanine (L-dopa), the precursor of dopamine. When given orally in large daily doses, some L-dopa is able to escape metabolism in the bloodstream and enter the brain, where surviving dopamine neurons convert it to dopamine. Although the degenerative changes are progressive, L-dopa may also be converted to dopamine by a specific enzyme. To increase the delivery of this dopamine precursor to the brain, L-dopa therapy is supplemented with carbidopa, an analogue of L-dopa that inhibits this enzyme in the intestine and in the general circulation but that is unable to penetrate into the brain. As a result, carbidopa increases the effectiveness of L-dopa. Overdosage with L-dopa can cause schizophrenia-like episodes, presumably due to the excess formation of dopamine. Some patients are also helped by bromocriptine (a dopamine-like agonist so modified as to be able to gain access to the brain). The use of L-dopa to treat Parkinson's disease, however, is not the radical cure that it was once thought to be but only a measure that modifies to some extent the degenerative changes of the disease. (F.E.Bl.)

CARDIOVASCULAR SYSTEM PHARMACOLOGY

Drugs that affect the function of the heart and blood vessels are among the most widely used in medicine. Although these drugs may exert their primary effect either on the blood vessels or on the heart itself, the cardiovascular system functions as an integral unit. Thus, drugs that affect blood vessels are often useful in treating conditions in which the primary disorder lies in the heart itself, or vice versa. Examples of disorders in which such drugs may be useful include hypertension (high blood pressure), angina pectoris (pain resulting from inadequate blood flow through the coronary vessels to the muscular wall of the heart), heart failure (inadequacy of the output of the heart in relation to the needs of the rest of the body), and arrhythmias (disturbances of cardiac rhythm).

Drug effects on the heart

Drugs affect the function of the heart in three main ways. They can affect the force of contraction of the heart muscle (inotropic effects); they can affect the frequency of the heartbeat, or heart rate (chronotropic effects); or they can affect the regularity of the heart beat (rhythmic effects).

Drugs affect blood vessels by altering the state of contraction of the smooth muscle in the vessel wall, altering its calibre, or diameter, thereby regulating the volume of blood flow. Such drugs are classified as vasoconstrictors if they cause the smooth muscle lining to contract, and vasodilators if they cause it to relax. Drugs may act directly on the smooth muscle cells, or they may act indirectly, for example by altering the activity of nerves of the autonomic nervous system that regulate vasoconstriction or vasodilation (see above *Autonomic nervous system pharmacology*). Another type of indirect mechanism is the action of vasodilator substances that work by releasing a smooth muscle relaxant substance from the cells lining the interior of the vessel. Some drugs mainly affect arteries, which control the resistance to blood flow in the vascular system, an important determinant of the arterial blood pressure; others mainly affect the veins, which control the pressure of blood flowing back to the heart, and hence the cardiac output (*i.e.*, the volume of blood pumped out by the heart per minute).

Inotropic agents. Inotropic agents are drugs that influence the force of contraction of cardiac muscle, thereby tending to affect the cardiac output. Drugs have a positive inotropic effect if they increase the force of contraction of the heart. The most important group of inotropic agents is the cardiac glycosides, substances that occur in the leaves of the foxglove (*Digitalis purpurea*) and other plants.

Although they have been used for many purposes throughout the centuries the effectiveness of cardiac glycosides in heart disease was established in 1785 by an English physician, William Withering, who successfully used an extract of foxglove leaves to treat heart failure. Many closely related glycosides with similar pharmacological actions are found in various plants, but they differ in ease of absorption from the gastrointestinal tract and in duration of action. The two compounds most often used therapeutically are digoxin and digitoxin.

Effects of cardiac glycosides

The most useful effect of cardiac glycosides is their ability to increase the force of contraction of cardiac muscle. They have, however, several additional effects, most of which are disadvantageous. These include a tendency to block conduction of the electrical impulse that causes contraction as it passes from the atria to the ventricles of the heart (heart block). Cardiac glycosides also have a tendency to produce an abnormal cardiac rhythm by causing electrical impulses to be generated at points in the heart other than the normal pacemaker region, the cells that rhythmically maintain the heartbeat. These irregular impulses result in ectopic heartbeats that are out of sequence with the normal cardiac rhythm. Occasional ectopic beats are harmless, but if this process continues to a complete disorganization of the cardiac rhythm (ventricular fibrillation), the pumping action of the heart is stopped, causing death within minutes unless resuscitation is carried out. Because the margin of safety between the therapeutic and the toxic doses of glycosides is relatively narrow, they must be used carefully.

Cardiac glycosides are believed to increase the force of cardiac muscle contraction by binding to and inhibiting the action of a membrane enzyme that extrudes sodium ions from the cell interior. Inhibiting the free flow of sodium ions from the interior of the cell across the membrane

to the exterior of the cell causes the intracellular sodium concentration to rise. The interior of the cell then becomes depolarized, or electrically less negative than normal with respect to the exterior of the cell. Because the cell is able to exchange sodium ions within the cell for calcium ions outside it, there is a secondary rise in intracellular calcium. This subsequently increases the force of contraction, since intracellular calcium ions are responsible for initiating the shortening of muscle cells.

The disturbances of rhythm that may be caused by cardiac glycosides result partly from the depolarization and partly from the increase in intracellular calcium. Because these rhythm disturbances are caused by the same underlying mechanism that causes the beneficial effect, there is no likelihood of finding a cardiac glycoside with a significantly better margin of safety. Apart from their cardiac actions, these glycosides tend to cause nausea and loss of appetite. Because digoxin and digitoxin have long plasma half-lives (two and seven days, respectively), they are liable to accumulate in the body. Treatment with either of these drugs must involve careful monitoring to avoid the adverse effects that may result from their slow buildup in the body.

The second type of inotropic agent that increases the force of cardiac muscle contraction includes epinephrine and norepinephrine. In addition to affecting the force of contraction, however, they also increase the heart rate. This, and the fact that they are quickly metabolized by the body and act only for a few minutes, means that they are not useful inotropic agents.

Caffeine-related drugs

The third type of inotropic agent that acts as a cardiac stimulant is the caffeine-related series of drugs represented by theophylline. Its action, like that of epinephrine, depends on an increase in the intracellular concentration of cyclic adenosine 3′,5′-monophosphate, which indirectly increases the influx of calcium ions into the cells, thereby increasing the force of contraction of cardiac muscle.

Chronotropic agents. The heart rate is controlled by the opposing actions of sympathetic and parasympathetic nerves and by the action of epinephrine released from the adrenal gland. Norepinephrine, released by sympathetic nerves in the heart, and epinephrine, released by the adrenal gland, increase the heart rate, while acetylcholine, released from parasympathetic nerves, decreases it. A competitive antagonist that acts to inhibit the stimulating action of norepinephrine on the heart is propranolol, which slows the heart and is often used to treat anginal attacks and disturbances of cardiac rhythm. Atropine blocks acetylcholine receptors and is used during anesthesia to prevent excessive cardiac slowing.

Antidysrhythmic drugs. Many types of heart disease lead to disturbances of the cardiac rhythm, a common example being the occurrence of ventricular dysrhythmias following heart attacks. Dysrhythmias are undesirable because they compromise the pumping action of the heart and because they can worsen suddenly and lead to cardiac arrest. The regularity of the heartbeat depends on the activity of the pacemaker area, located in the sinoatrial node of the heart, which generates electrical impulses at a frequency of 70 per minute. The rate is regulated by the opposing influences of the sympathetic and parasympathetic nerves. The impulse from the pacemaker spreads in an orderly sequence to the rest of the heart, resulting in a contraction of the atrial chambers, forcing the blood in these chambers into the ventricles. This is followed about 0.3 second later by contraction of the ventricles, the main pumping chambers, which forces the blood into the arteries.

Reentrant rhythms

The cardiac rhythm can be disturbed in several ways. (1) The conduction pathway may be disorganized, resulting in a reentrant rhythm in which an impulse circulates continuously in a local area of the heart (often a damaged region), causing irregular reexcitation of the rest of the heart at an abnormally high rate. If this happens in the atria it is called atrial fibrillation and the ventricular beat continues, though sometimes with an irregular rhythm. If this irregular heart rate occurs in the ventricles it is called ventricular fibrillation and the pumping action of the heart ceases. (2) Ectopic, or abnormally placed, pacemakers may appear in regions of the heart other than the sinoatrial node, and these can drive the heart at an abnormally high rate. (3) Various forms of heart block can occur in which the impulse fails to continue in the heart at some point because of local damage. This results in slowing or complete cessation of the heartbeat.

Drugs are useful in treating all of these types of dysrhythmia. Reentrant rhythm and ectopic pacemakers cause abnormally high heart rates (tachycardia), and they require treatment with drugs that slow the heart and reduce the electrical excitability of the muscle cells. Reentrant rhythms can be eliminated by increasing the refractory period of the cells, which is the interval following transmission of an electrical impulse during which the cell cannot be reexcited by another impulse. Increasing the refractory period has the effect of reducing the frequency at which impulses can be transmitted.

Quinidine and procainamide (mainly used for arterial dysrhythmias) and lidocaines and phenytoin (mainly used for ventricular dysrhythmias) exert their antidysrhythmic effects by reducing electrical excitability. Quinidine and procainamide have the disadvantage that they reduce the force of contraction of the heart and tend to lower blood pressure. They are also liable to cause side effects such as nausea and skin rashes. Lidocaine, which is also used as a local anesthetic, has a very short duration of action and must be given intravenously; its main use is in the prevention of ventricular dysrhythmias following acute occlusion of a coronary artery.

An important factor tending to exacerbate ectopic pacemakers is the release of norepinephrine from sympathetic nerves. Norepinephrine acts on β-adrenoceptors in the heart to increase its rate, which strongly increases the tendency for ectopic pacemakers to develop. Beta-adrenoceptor blocking drugs (*e.g.,* propranolol) are widely used to control these types of dysrhythmia because they slow the actions of the heart. They also tend to reduce the force of contraction of the heart, which can be a disadvantage, and they produce various other unwanted effects.

Calcium antagonists

In the mid-1970s, the calcium antagonists, another type of antidysrhythmic drug, were introduced. Verapamil and diltiazem are important examples of this class of drugs. They reduce the influx of calcium ions through the cell membrane, which normally occurs when the cell is depolarized. This movement of calcium ions across the membrane appears to be important as a factor in the genesis of reentrant rhythms and ectopic heartbeats. Inhibiting the influx of calcium ions is effective in controlling many types of dysrhythmia. Since calcium entry is essential for initiating the contraction of heart muscle cells, calcium antagonists tend to impair muscle contractility. Since calcium entry is also important in the contraction of blood vessel smooth muscle, calcium antagonists cause vasodilation and tend to lower arterial blood pressure.

All of the antidysrhythmic drugs discussed so far impair the conduction of the impulse for contraction from atria to ventricles and therefore can cause heart block. Antidysrhythmic drugs should be used carefully to avoid the various hazards and side effects that they may produce. Heart block causes a pathological slowing of the heart and is not usually treated with drugs, although β-adrenoceptor agonists such as isoproterenol are sometimes used in emergencies. An artificial electrical pacemaker device is usually fitted to provide effective long-term control.

Drugs affecting blood vessels. Many different drugs and endogenous substances cause constriction or dilation of blood vessels. Drugs that have a direct relaxant effect on vascular smooth muscle include the organic nitrates (*e.g.,* nitroglycerin tablets, which are mainly used to treat angina) and calcium antagonists (*e.g.,* nifidipine). Most blood vessels are controlled by the sympathetic nervous system, and they constrict in response to norepinephrine released from sympathetic nerves. Thus, drugs that affect the sympathetic system (see above *Autonomic nervous system pharmacology*) cause constriction or dilation of blood vessels. The parasympathetic nervous system is much less important in controlling blood vessels.

Apart from the actions of the sympathetic nervous system, several other physiological mechanisms regulate vascular

Renin-angiotensin system

smooth muscle. Of particular pharmacological importance are the renin-angiotensin system and locally acting vasodilator substances, such as histamine, bradykinin, and prostaglandins.

Renin is an enzyme that is released into the bloodstream by the kidney when the blood pressure falls. It acts on a plasma protein to produce a peptide, angiotensin I, which consists of a chain of 10 amino acids. This in turn is acted on by angiotensin converting enzyme (ACE) to produce an eight-amino acid peptide, angiotensin II (a potent vasoconstrictor), which raises the blood pressure. Inhibitors of ACE are used in treating high blood pressure.

Various substances that act on blood vessels are released when tissues are damaged by disease or injury. Histamine is stored by special cells in the skin and elsewhere, and when it is released histamine causes capillary walls to leak fluid, resulting in local tissue-swelling. Prostaglandins and bradykinin have similar functions. All of these substances apparently act locally in the process of inflammation rather than systemically in overall cardiovascular regulation.

Cardiovascular disease. In cardiac failure, cardiac glycosides are used for their inotropic effect on the heart, but vasodilators and drugs that increase urine flow (diuretics; see below *Kidney pharmacology*) are also helpful. The reduced cardiac output resulting from heart failure leads to an increase in pressure in the veins and also to accumulation of tissue fluid (edema). Vasodilators, such as the calcium antagonist nifedipine, dilate the veins and thus lower the venous pressure, and they also increase the cardiac output by reducing the resistance of the arterial system. Diuretic drugs are used to reduce the amount of tissue fluid, but they can also have a beneficial vasodilator effect. These drugs are used in treating high blood pressure as well.

High arterial blood pressure, which is produced by excessive constriction of small arteries, is often treated with drugs. Some drugs that lower blood pressure (hypotensives) inhibit the function of the sympathetic nervous system in various ways (see above *Autonomic nervous system pharmacology*). Hypotensive drugs include methyldopa and clonidine, which probably work at the level of the central nervous system; reserpine and guanethidine, which prevent the release of norepinephrine by sympathetic nerves; adrenoceptor-blocking drugs (*e.g.*, propranolol, which lowers blood pressure by reducing the cardiac output; and prazosin, which blocks the vasoconstrictor action of norepinephrine). Calcium antagonists also have a use in treating hypertension, as do other vasodilators such as hydralazine. A different approach, developed in the late 1970s, consists of using an inhibitor of adrenocortical extract (captopril), thus blocking the formation of angiotensin II. This is very effective in certain types of hypertension in which renin secretion is increased. Most antihypertensive drugs have a variety of unwanted effects, such as drowsiness, dizziness on standing (due to an excessive postural fall in arterial pressure), impotence, and allergic reactions. Though often fairly minor, side effects are a serious problem because of the long-term nature of antihypertensive therapy, and better drugs are constantly being sought.

Treatment of migraine

Migraine is a common condition associated with severe headaches that are believed to result from excessive dilation of the arteries in the membranous covering (meninges) surrounding the brain. The cause is not known, but it is believed to involve the local release of a substance called serotonin. Ergotamine, which comes from a fungus (ergot) that infests cereal crops and has a powerful vasoconstrictor effect, is widely used to treat migraine. Accidental poisoning with the ergot fungus produces many symptoms associated with excessive vasoconstriction, including brain disturbances and gangrene, but they do not generally occur when it is used therapeutically. Other antimigraine drugs include propranolol and calcium antagonists. Tests have shown them to be effective, but it is not clear how they work.

Partial occlusion of the coronary vessels by fatty deposits (atheroma) or blood clots may result in angina pectoris, a pain that occurs when the blood supply to the heart is inadequate for its needs. Vasodilator drugs, particularly nitroglycerine tablets and calcium antagonists, are often used to relieve this condition. They work in part by dilating arteries and veins, which reduces arterial blood pressure and cardiac output, thereby lowering the work and oxygen consumption of the heart. They also have some effect on the coronary vessels themselves and many direct blood toward the regions in which the flow is impaired. Propranolol is also effective because it reduces the rate and force of the heart, thus lowering its oxygen requirement.

(H.P.R.)

DRUGS AFFECTING BLOOD

When a small blood vessel is cut, a repair mechanism (hemostasis) is activated that eventually seals the cut and prevents further blood loss. What is in fact a lifesaving mechanism that protects the wounded body from hemorrhage becomes life threatening when clots (thrombi) form within functional blood vessels (thrombosis). Thrombosis tends to occur in blood vessels damaged by arteriosclerosis or in vessels with a sluggish blood flow. In veins, portions of the thrombi (emboli) may break off and pass along the bloodstream to become lodged in the arteries of the heart. The drugs described in this section either inhibit hemostasis or they act to enhance the mechanisms that lyse, or dissolve, thrombi.

The clotting process

The clotting process essentially involves the conversion of a soluble plasma protein, fibrinogen, into strands of the insoluble protein fibrin, which forms a mesh that traps platelets. The trigger for hemostasis is an injury to the endothelium, the cells lining the blood vessels, so that the underlying layer of collagen is exposed. The series of events leading to clot formation in a cut blood vessel are (1) constriction of the blood vessel by serotonin, epinephrine, and the thromboxane A_2, which diminishes blood loss; (2) formation of a plug of platelets (the platelet phase) by ADP and thromboxane A_2, also released by platelets, which act in a positive feedback process that makes more platelets adhere to the collagen and to each other; and (3) the conversion of the plug into a clot of fibrin (the coagulation phase). The formation of fibrin entails the sequential interaction of more than a dozen clotting factors, which are protease enzymes (*i.e.*, they accelerate the breakdown of proteins). Each of these clotting factors activates the next in a coagulation cascade of proteolytic reactions that break down protein molecules. The penultimate reaction is the conversion of the soluble fibrinogen to soluble fibrin under the influence of the enzyme thrombin (factor IIa). Soluble fibrin is converted to insoluble fibrin strands by activated factor XIII (fibrin-stabilizing factor), and covalent cross-linkages form between the fibrin strands to give a strong and rigid network. Several of the clotting factors (II, VII, IX, X) require the presence of vitamin K for their activation. Consequently, inhibition of vitamin K blocks the propagation of coagulation pathways.

Under normal conditions the adhesion of platelets to vessel walls is prevented by the vascular endothelial cells, at least in part by their ability to release prostaglandins called prostacyclin or prostaglandin I_2, which reduce platelet stickiness and cause dilation of the blood vessels.

A fibrinolytic system exists in the body that restricts thrombus propagation beyond the site of injury and is also involved in the lysis of clots as wounds heal. The fibrinolytic system degrades fibrin and fibrinogen to products that act to inhibit the enzyme thrombin. The active enzyme involved in the fibrinolytic process is plasmin, which is formed from its precursor, plasminogen, under the influence of an activating factor released from endothelial cells. If formed in the circulating blood, plasmin is normally inhibited by a circulating plasmin inhibitor.

Anticoagulant drugs. Anticoagulant drugs prevent the formation of thrombi by inhibiting the coagulation phase. They are used to prevent the formation and spread of venous and arterial thrombi; however, they are ineffective against existing thrombi. Anticoagulant therapy is used to treat deep-vein thrombosis and pulmonary embolism arising after immobilization or surgery; systemic or coronary arterial embolism caused by heart diseases or replacement of the prosthetic valve; and disseminated intravascular coagulation, which is a systemic activation of the coagulation

system that leads to consumption of coagulation factors and hemorrhage.

Heparin

Heparin, used primarily in hospitalized patients, is a mixture of negatively charged mucopolysaccharides. An endogenous substance whose physiological role is not understood, heparin blocks the coagulation cascade by promoting the interaction of a circulating inhibitor of thrombin (antithrombin III) with activated clotting factors. Because it is not well absorbed when taken orally, heparin is given intravenously to inhibit coagulation immediately; the onset of the drug's effect is delayed after subcutaneous administration. Heparin is not bound to plasma proteins, it is not secreted into breast milk, and it does not cross the placenta. The drug's action is terminated by metabolism in the liver and excretion by the kidney. The major side effect associated with heparin is hemorrhage; thrombocytopenia (reduced number of circulating platelets) and hypersensitivity reactions also occur. Oral anticoagulants and heparin have additional anticoagulant effects. Heparin-induced hemorrhage may be reversed with the antagonist protamine, a positively charged protein that has a high affinity for heparin's negatively charged molecules, thus neutralizing the drug's anticoagulant effect. When given in combination with heparin, dihydroergotamine, which constricts veins and increases blood flow, increases heparin's antithrombotic effect.

Oral anticoagulants

Oral anticoagulants are derivatives of 4-hydroxycoumarin (coumarin) or indan-1,3-dione (indandione). Structurally the coumarin derivatives resemble vitamin K, an important element in the synthesis of a number of clotting factors. Interference in the metabolism of vitamin K in the liver by coumarin derivatives gives rise to clotting factors that are defective and incapable of binding calcium ions (another important element in the activation of coagulation factors at several steps in the coagulation cascade). When anticoagulants are taken orally, several hours are required for the onset of the anticoagulant effect because time is required both for their absorption from the gastrointestinal tract and for the clearance of biologically active clotting factors from the blood. Warfarin, the most commonly used oral anticoagulant, is rapidly and almost completely absorbed; the absorption of dicumarol and other anticoagulant agents, however, is slower and less consistent.

Oral anticoagulants bind extensively to plasma proteins, have relatively long plasma half-lives, and are metabolized by the liver and excreted in the urine and feces. They may cross the placenta to cause fetal abnormalities or hemorrhages in neonates; their appearance in breast milk apparently has no adverse effect on nursing infants. Hemorrhage is the principal toxic effect during oral anticoagulant therapy, but each of the coumarin derivatives causes its own idiosyncratic side effects. Vitamin K, when given intravenously to promote the synthesis of functional clotting factors, stops bleeding after several hours. Plasma that contains normal clotting factors is given to control serious bleeding. Oral anticoagulants may interact adversely with other drugs that bind to plasma proteins or are metabolized by the liver.

Drugs affecting platelets. Platelet aggregates and thrombi formed in coronary arteries may cut off the blood supply to a region of the heart and precipitate a myocardial infarction (heart attack). When administered shortly after a heart attack, drugs affecting platelets can reduce the extent of damage to the heart muscle and the incidence of immediate reinfarction and death. They act in different ways, and the long-term (five-year) benefit of immediate postinfarction therapy is uncertain.

Cyclooxygenase

Aspirin, a non-narcotic analgesic, antipyretic, and anti-inflammatory agent, inhibits an enzyme (cyclooxygenase) involved in the production of thromboxane A_2 in platelets and of prostacyclin in the endothelial cells that line the heart cavities and walls of the blood vessels. Cyclooxygenase is synthesized by endothelial cells but not by platelets. The goal of aspirin therapy is to neutralize cyclooxygenase only in platelets, which inhibits thromboxane A_2 synthesis and therefore platelet aggregation, but to continue the production of cyclooxygenase and prostacyclin in endothelial cells. This is accomplished with a low dose. The occurrence of coronary embolization and the incidence of acute myocardial infarction and death are reduced with the administration of low-dose aspirin therapy. In large aspirin doses, cyclooxygenase synthesis is inhibited in endothelial cells as well as in platelets.

Dipyridamole, a coronary artery vasodilator, decreases platelet adhesiveness to damaged endothelium. The drug prevents platelet aggregation and release by increasing the concentration of platelet cyclic adenosine monophosphate (cAMP) in two ways: by inhibiting an enzyme (phosphodiesterase) that degrades cAMP and by increasing the stimulating effect of prostacyclin on an enzyme (adenylate cyclase) that synthesizes cAMP. Dipyridamole alone does not reduce the incidence of death following myocardial infarction, but it works effectively in combination with other inhibitors of platelet function or with anticoagulants.

Dextran is a plasma volume expander that coats platelets and the blood vessel endothelium, reducing platelet adhesiveness. Dextran reduces the formation of thrombi by increasing their susceptibility to fibrinolysis, and it reduces blood viscosity and dilutes coagulation factors through an osmotic effect. Dextran is similar in effectiveness to heparin and warfarin for preventing venous and pulmonary thromboembolism.

Sulfinpyrazone, a nonsteroidal anti-inflammatory agent, inhibits platelet cyclooxygenase. It has no effect on platelet aggregation but it does prolong platelet revival time. The drug decreases the incidence of postinfarction sudden death, an effect that may be due to an undiscovered aspect of the drug's action unrelated to its effect on platelets.

Drug combinations

Certain drug combinations can be useful for preventing thromboembolism even when the individual agents are without real effect. These combinations include dipyridamole with aspirin or oral anticoagulants after replacement of a prosthetic heart valve; aspirin with dipyridamole after myocardial infarction; and aspirin with sulfinpyrazone after hip surgery.

Fibrinolytic drugs. Fibrinolytic drugs activate the fibrinolytic pathway and lyse clots. The fibrinolytic drugs are distinct from the coumarin derivatives and heparin, which inhibit the formation of clots.

Streptokinase is produced from streptococcal bacteria. When administered systemically, streptokinase lyses acute deep-vein, pulmonary, and arterial thrombi; however, the drug is less effective in treating chronic occlusions. Streptokinase administered by intracoronary artery infusion soon after a coronary occlusion has formed is effective in reestablishing the flow of blood through the heart and vessels after a myocardial infarction and in limiting the size of the area of infarct (or tissue death). Intracoronary infusion permits the delivery of a high concentration of the drug to a localized area and speeds the activation of the fibrinolytic pathway. Intracoronary infusion minimizes the amount of streptokinase inactivated by antibodies that are normally present in blood. Heparin, aspirin, and/or dipyridamole can be added to therapy to help prevent the recurrence of occlusive thrombi. An overdose of streptokinase may lead to bleeding from systemic fibrinogenolysis, which is the breakdown of the coagulation factors by plasmin.

Urokinase is a protease enzyme that activates plasminogen directly. Because it is obtained from tissue culture of human kidney cells, it is not antigenic. Urokinase lyses recently formed pulmonary emboli, and, compared to streptokinase, it produces fibrinolysis without extensive breakdown of the coagulation factors. The usefulness of intravenous or intracoronary urokinase after myocardial infarction is not known.

Tissue plasminogen activator (t-PA) stimulates fibrinolysis, and it has several important advantages over streptokinase and urokinase in treating coronary thrombosis. It binds readily to fibrin and after intravenous administration activates only the plasminogen that is bound to the thrombus; thus, fibrinolysis occurs in the absence of an extensive breakdown of the coagulation factors. It may be used to initiate treatment of heart attack victims en route to the hospital, eliminating the time spent in the hospital preparing the patient for intracoronary injections of streptokinase. This is extremely useful because the rapid reestablishment of coronary blood flow is critically impor-

tant to minimize the amount of damage to myocardial cells after an infarction.

An elevation in the level of circulating plasmin because of excessive activation of the fibrinolytic system may result in fibrinogenolysis and hemorrhage. The antifibrinolytic drug aminocaproic acid is a specific antagonist of plasmin and inhibits the effects of fibrinolytic drugs. (J.S.F.)

DRUGS AFFECTING MUSCLE

Functions of smooth muscle

Smooth muscle. Smooth muscle is found primarily in the internal body organs and performs many functions, including control of the diameter, or calibre, of blood vessels, control of the propulsive activity of the gastrointestinal tract, contraction of the urinary bladder, contraction of the uterus, control of ocular focusing and pupil diameter, and control of the calibre of the respiratory airways. Whereas striated, or skeletal, muscle is controlled from the central nervous system by way of somatic motor nerves, smooth muscle is controlled by the autonomic nervous system and by hormones. In many situations, smooth muscle undergoes spontaneous, often rhythmic, contractions that are not dependent on outside nerve impulses. Smooth muscle contracts much more slowly than striated muscle and in general shows a much broader sensitivity to drugs.

Smooth muscle contraction is initiated by depolarization (the sharp influx of positively charged ions) of the cell membrane. This causes calcium-selective ion channels in the membrane to open, allowing calcium to flow into the cell. The contractile mechanism of smooth muscle cells, like that of striated muscle, involves the sliding action of overlapping protein filaments composed of actin and myosin molecules. The free calcium ions diffuse to the myosin and activate its enzymatic activity, which begins the process of contraction. Most of the drugs that stimulate or inhibit smooth muscle contraction do so by regulating the concentration of intracellular calcium, but other intracellular messengers such as cyclic adenosine monophosphate (cAMP) and cyclic guanosine monophosphate (cGMP) are also involved (see above *General principles*).

The main classes of drugs with important effects on smooth muscle are shown in Table 3. Adrenoceptor agonists, muscarinic agonists, nitrates, and calcium antagonists are considered in other sections and are not discussed here.

Table 3: Drugs Affecting Smooth Muscle

agent	contraction	relaxation
autonomic drugs:		
β-adrenoceptor agonists		GI tract bronchi blood vessels uterus
α-adrenoceptor agonists	blood vessels pupil dilator muscle	
muscarinic agonists	GI tract bladder bronchi pupil constrictor muscle ocular focusing muscle	
local hormones:		
histamine	bronchi GI tract	small blood vessels
bradykinin	bronchi GI tract large blood vessels	small blood vessels
prostaglandins		
PGE series	GI tract uterus	bronchi small blood vessels
PGF series	bronchi uterus GI tract	
oxytocin	uterus milk ducts	blood vessels
drugs:		
nitrates		all smooth muscle, especially large blood vessels
Ca antagonists		blood vessels
ergotamine	uterus blood vessels	
ergometrine	uterus	
papaverine		all smooth muscle
morphine	GI tract (spasm) bronchi	
theophylline		bronchi blood vessels

Several local hormones that are released from cells or formed in tissue act on target cells in close proximity to each other. Because they are destroyed rapidly in the bloodstream they do not function as true blood-borne hormones. Local hormones are usually formed in response to tissue injury, and they are partly responsible for inflammatory and allergic reactions. Smooth muscle responses (*e.g.*, constriction, vasodilation, and edema), particularly in blood vessels and bronchi, are an important component of such reactions. Apart from histamine (see above *Drugs affecting blood*) the main agents known to function as local hormones are kinins and prostanoids.

Kinins

The kinins are peptides that are formed by the enzymatic cleavage of a plasma protein. This cleavage occurs when an enzyme, also present in plasma, is activated in the presence of damaged tissue. Bradykinin, a peptide consisting of a chain of nine animo acids, is an extremely potent vasodilator. Elsewhere in the body, however, bradykinin contracts smooth muscle, particularly in the bronchi and gastrointestinal tract. It also causes the secretion of fluid from the walls of these structures. Constriction of smooth muscle in the bronchi and increased fluid secretion contribute to the airway obstruction that occurs in an asthmatic attack. Bradykinin is probably the causative agent of asthma as well as diarrhea, since similar mechanisms of action occur in the intestine. Bradykinin has no therapeutic uses, but if developed, a selective antagonist of bradykinin might be a useful drug to block its inflammatory and allergic reactions.

Prostanoids (prostaglandins) and leukotrienes (a related group of lipids) are derived by enzymatic synthesis from one of three 20-carbon fatty acids, with the most important in humans being arachidonic acid, a constituent of cell membranes. When a membrane enzyme, phospholipase C, is activated, arachidonic acid is released and converted by intracellular enzymes to unstable intermediates, which are further metabolized, depending on the group of enzymes involved, to prostanoids or leukotrienes. The synthesis and release of prostanoids and leukotrienes occurs when cells are damaged, even mildly. They are important in producing tissue responses to injury as well as in other physiological reactions. Derivatives of prostanoids have as their basic structure a five-carbon ring with two side chains, and they differ from each other in the substitutions on the ring structure. The derivatives are distinguished by the letters A through I. In relation to smooth muscle, the most important prostanoids are prostaglandins E_1, E_2, and F_2 (the subscript numbers denoting the 20-carbon precursor and the number of double bonds in the molecule) and leukotrienes C_4 and D_4; the most important sites of action are bronchial and uterine smooth muscle (see Table 3). Leukotrienes are powerful bronchoconstrictors, and they are believed to be synthesized and released during asthmatic attacks. Prostaglandins in minute amounts produce a broad range of physiological effects in almost every system of the human body. Prostaglandins E_1 and E_2 are dilators, and prostaglandins of the F series are bronchoconstrictors. Prostaglandin E_1 also dilates blood vessels, and it is sometimes administered by intravenous infusion to treat peripheral vascular disease. Most prostaglandins cause uterine contraction, and they are sometimes administered to initiate labour (see below *Reproductive system pharmacology*).

Derivatives of ergot

Ergot alkaloids (see above *Cardiovascular system pharmacology*) are produced by a parasitic fungus that grows on cereal crops. Among the many biologically active constituents of ergot, ergotamine and ergometrine are the most important. The main effect of ergotamine is to constrict blood vessels, which can be so intense as to cause gangrene of fingers and toes, giving rise to the name St. Anthony's Fire for the syndrome produced by ergot poisoning. Dihydroergotamine, a derivative, is used in treating migraine (see above *Cardiovascular pharmacology*). Ergometrine has much less effect on blood vessels but a stronger effect on the uterus. It can induce abortion,

though not reliably. Its main use is to promote a strong uterine contraction immediately after parturition, thus reducing the likelihood of bleeding. Both ergotamine and ergometrine cause smooth muscle to contract.

Morphine, an opioid widely used for its painkilling properties, causes smooth muscle contraction in certain situations, which gives rise to some of its side effects. It contracts bronchial smooth muscle (probably by releasing histamine) and may precipitate an attack of asthma. It also causes spasm of the sphincters of the gastrointestinal tract, giving rise to constipation, and spasm of the biliary and urinary tracts. It is therefore not generally suitable for treating pain associated with renal or biliary stones.

Skeletal muscle. Skeletal muscle contracts in response to electrical impulses that are conducted along motor nerve fibres originating in the brain or spinal cord. The motor nerve fibres reach the muscle fibres at sites called motor end plates, located roughly in the middle of each muscle fibre. The motor end plate stores vesicles of the neurotransmitter acetylcholine. An impulse arriving at the motor end plate causes many acetylcholine-containing vesicles to be discharged into the narrow synaptic cleft between the end plate and the membranes of the muscle fibre. Acetylcholine binds to nicotinic receptors on the muscle fibre membrane, causing ion channels to open and allowing a local influx of positively charged ions into the muscle fibre. The muscle fibre is thus depolarized (*i.e.*, its internal potential becomes less negative), and if this local depolarization is large enough a propagated electrical impulse is set up that activates the contractile machinery along the whole length of the fibre. The process occurs within one to two milliseconds (msecs). The released acetylcholine is inactivated within one msec by the action of the enzyme acetylcholinesterase, which is located in the synaptic cleft. The process normally has a large margin of safety because the amount of acetylcholine released is more than enough to activate the muscle fibre.

Drug action on neuromuscular junction

Because the contractile mechanism of skeletal muscles is relatively insensitive to drug action, the most important group of drugs that affect the neuromuscular junction act on (1) acetylcholine synthesis, (2) acetylcholine release, (3) acetylcholine receptors, or (4) acetylcholinesterase.

Hemicholinium and botulinum toxin each cause neuromuscular paralysis by blocking acetylcholine synthesis and acetylcholine release, respectively (see above *Autonomic nervous system pharmacology*). There are a few drugs that facilitate acetylcholine release, including tetraethylammonium and 4-aminopyridine. They work by blocking potassium-selective channels in the nerve membrane, thereby prolonging the electrical impulse in the nerve terminal and increasing the amount of acetylcholine released. This can effectively restore transmission under certain conditions, but these drugs are not selective enough for their actions to be of much use therapeutically.

Neuromuscular blocking drugs act on acetylcholine receptors and fall into two distinct groups: nondepolarizing (competitive) and depolarizing blocking agents.

Competitive neuromuscular blocking drugs act as antagonists at acetylcholine receptors, reducing the effectiveness of acetylcholine in generating an end-plate potential. When the amplitude of the end-plate potential falls below a critical level, it fails to initiate an impulse in the muscle fibre, and transmission is blocked. The most important competitive blocking drug is tubocurarine, which is the active constituent of curare, a drug with a long and romantic history and one of the first drugs whose action was analyzed in physiological terms. Claude Bernard, a 19th-century French physiologist, showed by experiment that curare causes paralysis by blocking transmission between nerve and muscle, without affecting nerve conduction or muscle contraction directly. Curare is a product of plants (mainly *Chondodendron* species) that grow primarily in South America and has been used there for centuries as an arrow poison. Tubocurarine is a complex molecule containing two basic groups that are thought to bind to the receptor in the same way that acetylcholine does.

Anesthetic actions of tubocurarine

Tubocurarine is used in anesthesia to produce the necessary level of muscle relaxation. It is given intravenously, and the paralysis lasts for about 20 minutes, although some muscle weakness remains for a few hours. After it has been given, artificial ventilation is necessary because breathing is paralyzed. Tubocurarine tends to lower blood pressure by blocking transmission at sympathetic ganglia, and, because it can release histamine in tissues, it also may cause constriction of the bronchi. Synthetic drugs are available that have fewer unwanted effects—for example, gallamine and pancuronium. The action of competitive neuromuscular blocking drugs can be reversed by anticholinesterases, which protect acetylcholine against rapid hydrolysis and can increase the amplitude of the end-plate potential enough to restore effective transmission. This is a useful way to restore muscle function at the end of a surgical operation.

Anticholinesterase drugs (see above *Autonomic nervous system pharmacology*) inhibit the rapid destruction of acetylcholine at the neuromuscular junction and thus enhance its action on the muscle fibre. Normally this has little effect, but in the presence of a competitive neuromuscular blocking agent, transmission can be restored. This provides a useful way to terminate paralysis produced by tubocurarine or similar drugs at the end of surgical operations. Neostigmine often is used for this purpose, and atropine is given simultaneously to prevent the parasympathetic effects that are enhanced when acetylcholine acts on muscarinic receptors.

Anticholinesterase drugs also are useful in treating myasthenia gravis, in which progressive neuromuscular paralysis occurs as a result of the formation of antibodies against the acetylcholine receptor protein. The number of functional receptors at the neuromuscular junction becomes reduced to the point where transmission fails. Anticholinesterase drugs are effective in this condition because they enhance the action of acetylcholine and enable transmission to occur in spite of the loss of receptors; they do not affect the underlying disease process. Neostigmine and pyridostigmine are the drugs most often used because they appear to have a greater effect on neuromuscular transmission than on other cholinergic synapses, and this produces fewer unwanted side effects. The immune mechanism responsible for the inappropriate production of antibodies against the acetylcholine receptor is not well understood, but the process can be partly controlled by treatment with steroids or immunosuppressant drugs such as azathioprine.

Depolarizing neuromuscular blocking drugs, of which succinylcholine is the only important example, act in a more complicated way than nondepolarizing, or competitive, agents. Succinylcholine has an action on the end plate similar to that of acetylcholine. When given systemically, it causes a sustained end-plate depolarization, which first stimulates muscle fibres throughout the body, causing generalized muscle twitching. Within a few seconds, however, the maintained depolarization causes the muscle fibres to become inexcitable, so that they fail to respond to nerve stimulation. The paralysis lasts for only a few minutes because the drug is quickly inactivated by cholinesterase in the plasma. Succinylcholine often is used to produce paralysis quickly at the start of a surgical operation (and then is supplemented later with a competitive blocking agent) or for brief surgical procedures. It is used widely, despite a number of disadvantages. Generalized muscle aches are commonly experienced for a day or two after recovery. More seriously, a small proportion of people (about one in 3,000) have abnormal plasma cholinesterase and may remain paralyzed for a long time. Succinylcholine also causes the release of potassium ions from muscles and an increase in the concentration of potassium in the plasma. This happens particularly in patients with severe burns or trauma in whom it can cause potentially dangerous cardiac disturbances. Another hazard is the development of malignant hyperthermia, a sudden rise in body temperature caused by increased tissue metabolism. This condition is very rare, but it is often fatal if not treated rapidly enough. (H.P.R.)

Paralytic effect of succinylcholine

DIGESTIVE SYSTEM PHARMACOLOGY

Drugs may act on the gastrointestinal tract either by affecting the actions of the involuntary muscle (motility) and thus altering movement or by altering the secretion of

digestive juices. The former drugs may be used to combat diarrhea, constipation, or vomiting.

Drugs affecting gastrointestinal motility. *Diarrhea.* Diarrhea is the frequent passage of a watery, unformed stool. Its causes range from serious organic disease to mental stress. In the treatment of diarrhea, kaolin powder is the most widely used adsorbent powder. Kaolin is a naturally occurring hydrated aluminum silicate, which is prepared for medicinal use as a fine powder. It is suggested that kaolin binds and thus inactivates poisons that may be in the gastrointestinal tract. It is not harmful, and it is effective in many cases if taken in large enough doses (*e.g.*, an initial dose of two to 10 grams followed by the same amount after every bowel movement).

Treatment

Morphine, codeine, and the synthetic opiates and their analogues have a constipating action (morphine was used for this effect long before it was used as a painkiller). The dangers of dependency and addiction clearly prevent the use of certain opiates (*e.g.*, morphine, meperidine, and heroin) as a treatment for diarrhea. Other opiates (codeine and the synthetic analogues diphenoxylate and loperamide) produce little dependence, however, and they have been used successfully in the treatment of diarrhea. Diphenoxylate in combination with atropine has been used by astronauts to reduce bowel movements.

Constipation. There are four kinds of medication available for relief of constipation: saline purgatives, fecal softeners, contact purgatives, and bulk laxatives.

Saline purgatives are salts containing multivalent ions. These highly charged ions do not readily cross cell membranes, and hence they remain inside the lumen, or passageway, of the bowel. They retain water through osmotic forces. The volume of the contents of the bowel is thus increased, stretching the colon and producing a normal stimulus to contraction of the muscle, which leads to defecation. Some commonly used salts are magnesium sulfate (Epsom salts), magnesium hydroxide, sodium sulfate (Glauber's salt), and potassium sodium tartrate (Rochelle salt or Seidlitz powder).

Fecal softeners are not absorbed from the alimentary canal. They act to increase the bulk of the feces. Two are used. The first is liquid paraffin (mineral oil), used either as the oil itself or as a white emulsion. The second group contains drugs with a detergent action. These drugs produce fecal softening in one or two days by increasing the penetration of the stool by water.

Purgatives

Purgatives are drugs whose exact mechanism of action is unknown. They include the anthraquinone derivatives (cascara, aloe, senna, and rhubarb), phenolphthalein, and ricinoleic acid (castor oil). These drugs, frequently used by older people, irritate the lining of the bowel, which may account for their effect. After regular use, their effect tends to lessen, so that larger and more frequent doses are necessary until finally they cease to be effective. They are useful, however, when short-term purging is required (*e.g.*, before surgery or after an illness).

Bulk laxatives act by increasing the size of the feces, in part because of their capacity to attract water. This group includes methylcellulose and carboxymethylcellulose, the gums agar and tragacanth, psyllium (plantago) seed, and dietary fibre.

Vomiting. Emetics produce nausea and vomiting, and their use is limited to the treatment of poisoning with certain toxins that have been swallowed. The most commonly used drugs for this purpose are ipecac syrup, prepared from the dried roots of *Cephaelis ipecacuanha*, a plant indigenous to Brazil and Central America, and apomorphine, a derivative of morphine.

Antiemetics are drugs that prevent vomiting. Broadly, they may be divided into two groups: drugs that are effective in combating motion sickness and drugs that are effective against nausea and vomiting due to other causes. The exact way in which these drugs work is not known. They may act by depressing the chemoreceptor trigger zone in the hypothalamus that controls vomiting.

Drugs that are effective against motion sickness are the anticholinergic drugs and the antihistamines. Although many are available for use, none is entirely free from side effects (*e.g.*, dry mouth and blurred vision with the anticholinergics; drowsiness with the antihistamines). The most effective drugs in this group are the anticholinergic drug scopolamine and the antihistaminic drug promethazine, although many other analogues are used widely.

Nausea and vomiting other than that associated with motion sickness are present in many diseases; *e.g.*, radiation sickness, postoperative vomiting, and liver disease. In these cases, the most effective antiemetics are the phenothiazines (also used in psychiatric medicine) and metoclopramide.

Drugs affecting digestive juices. It has long been thought that gastric and duodenal ulcers are related to the production of acid. Hydrochloric acid is a natural element in the stomach, and excess levels of it, together with the enzyme pepsin, quickly produce ulceration unless the stomach wall is protected. Although investigations have demonstrated that many other factors may play a role in the development of peptic ulcer (*e.g.*, immunological factors and personality type), measures designed to prevent the action of hydrochloric acid on the mucosa is still the cornerstone of therapy. These measures include preventing secretion of acid and neutralization of acid in the stomach by antacids.

Acid secretion. Acid secretion can be prevented by blocking acetylcholine, the neurotransmitter that stimulates acid secretion. The drugs that block the actions of acetylcholine have many side effects (dry mouth, blurred vision, difficulty in passing urine), and although several analogues have been produced only a few have been adequately demonstrated to block gastric acid secretion; they include atropine sulfate and hyoscine. In 1972 a new group of drugs that block gastric acid secretion was discovered; these were called H_2 blockers and include cimetidine and ranitidine (see below *Histamine and antihistamines*). In patients with duodenal ulcers, H_2 blockers administered for four to six weeks dramatically increase the healing of the ulcer and also reduce the pain. Low maintenance doses lower the recurrence rate of duodenal ulcer.

H_2 blockers

Neutralization. Excess acid may be neutralized in the stomach with antacid tablets and mixtures. Antacids do relieve pain, and they have been used since the time of Pliny for this purpose. It has not been proved that they have any effect on the healing of the ulcer. The main constituents of antacids are aluminum and magnesium hydroxides. There are three side effects of antacid therapy, which depend on the compound used. First, many have an action on the bowel; some have a mild laxative effect and some are constipating. Second, if the positively charged compounds are absorbed, the blood may be made alkaline. Third, antacid therapy may affect the absorption of other drugs by binding with them in the gastrointestinal tract.

Mucosal barrier. The mucosal barrier is the name given to the barrier in the stomach that resists the back-diffusion of hydrogen ions. The barrier is a layer of thick mucus secreted together with an alkaline fluid. Since the mucus is a gel, it entraps the alkaline fluid so that the stomach is coated with a tenacious, slimy, alkaline coat. It is probably the integrity of the barrier that is the most important protection the stomach has against attack by acid and pepsin. Many substances attack the mucosal barrier; these include bile, some drugs including salicylates, and substances in the diet. Alcohol has a particularly devastating effect on the barrier, which explains the gastritis (inflammation of the stomach lining) that often follows excess drinking.

There is a group of drugs that have the effect of strengthening the mucosal barrier. These are mainly based on licorice, which has been used in Europe for many years for the treatment of indigestion. Carbenoxolone, a synthetic compound derived from naturally occurring substances in licorice root, significantly increases the rate of healing of peptic ulcers, especially gastric ulcers. The disadvantage of the drug is its side effects; in about one-third of patients it raises the blood pressure and produces fluid retention and potassium loss. These rather serious side effects have led to the development of similar drugs to promote ulcer healing with reduced side effects. (M.A.Su.)

REPRODUCTIVE SYSTEM PHARMACOLOGY

Several sites in the human reproductive system are either vulnerable to chemicals or can be manipulated by drugs.

Within the central nervous system, sensitive sites include the hypothalamus (and adjacent areas of the brain) and the anterior lobe of the pituitary gland. Regions outside the brain that are vulnerable include the gonads (*i.e.*, ovary or testis), the uterus in the female, and the prostate in the male.

Barriers against drugs

The body has anatomical or physiological barriers that tend to protect the reproductive system. The so-called placental barrier and the blood–testis barrier impede certain chemicals, although both allow most fat-soluble chemicals to cross. Drugs that are more water soluble and that possess higher molecular weights tend not to cross either the placental or the blood–testis barrier. In addition, if a drug or chemical binds to a large molecule such as a blood-borne protein, it is less likely to be transported into the testes or less likely to come in contact with the fetus. There appears to be little, if any, barrier to chemicals or drugs gaining entry to breast milk or semen.

Female reproductive system. *Oral contraceptives.* Oral contraceptives, universally known as "the Pill," constitute a class of synthetic steroid hormones. They are capable of suppressing the release of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior lobe of the pituitary gland. Known collectively as gonadotrophic hormones, FSH and LH are capable of stimulating the release of progesterone and estrogen from the gonads, or ovaries; all of these hormones are responsible for modulating the female menstrual cycle. Ovulation is believed to be related to a midcycle release of LH, which can be effectively suppressed or blocked by the systematic administration of synthetic hormones. There are many commercial preparations of oral contraceptives, but most of them contain a combination of an estrogen (usually ethinyl estradiol) and a progestin (commonly norethindrone). In general, oral contraceptives are taken in a monthly regimen that parallels the menstrual cycle. Protection from pregnancy is often unreliable until the second or third drug cycle, and during this time certain side effects such as nausea, breast tenderness, or breakthrough bleeding may be evident. More serious side effects, including venous and arterial thromboembolism and a rise in blood pressure, are possible, especially in women over 34 years of age. Normal ovulation usually commences two to three months after stopping the Pill.

Progestin-only preparations (the so-called Minipill) thicken the mucus lining of the cervix and make it more acidic, thereby rendering it hostile to the male spermatozoa. Progestin-only preparations are somewhat less reliable than the combination preparations but produce fewer side effects. Under certain circumstances, the progestin may be administered as an intramuscular deposit that gradually releases the hormone over the course of one to three months.

The Morning-After Pill

Short courses of a high-dose estrogen (the so-called Morning-After Pill) may be taken after coitus. It increases the activity of the fallopian tubes so that the fertilized egg is expelled into the uterus before the uterus has undergone the modification necessary to receive it. This type of contraceptive produces a great deal of nausea and vomiting.

Apart from oral contraceptives, no other drugs are used therapeutically to affect ovarian function. Some drugs may have undesirable side effects on the ovary, which often culminate in menstrual irregularities. Certain tranquilizers (*e.g.*, reserpine and chlorpromazine), narcotics, and anticancer drugs can adversely affect the hormonal secretions of the ovary.

Oxytocin drugs. Oxytocin occurs naturally as a hormone secreted by the posterior lobe of the pituitary gland or it can be made synthetically. Physiologically, it promotes the secretion of breast milk and stimulates the contraction of the uterus during labour. Oxytocin can also be given to control bleeding after childbirth, although one of the ergot alkaloids (*e.g.*, methylergonovine) is more commonly used. Oxytocin can be administered intravenously, sublingually, or by nasal spray.

Teratogenicity. If the fetus is exposed in the uterus to certain environmental chemicals, infections, or drugs, it may develop abnormalities. The toxic substance is described as teratogenic (literally, "monster-producing"), and the study of this type of toxicity is called teratology. About 3 percent of developmental abnormalities have been proved to be drug-induced. It is wise to avoid all drugs (including nicotine) during pregnancy, unless the medicine is well tried and essential. Drugs taken by male partners may be teratogenic if they damage the genetic material (chromosomes) of the spermatozoa.

Male reproductive system. The only male reproductive organ that is a target of pharmacologic manipulation is the prostate gland. This accessory sex organ is susceptible to both benign and malignant changes that seem to be linked to age. The prostate gland is affected by the general class of hormones called androgens, which comprise the male sex hormones. A chemical class of drugs known as antiandrogens is used therapeutically to treat selected pathologic changes in the prostate, which usually include an increase in growth. Antiandrogens can be subdivided into those drugs that contain inherent hormonal properties (*e.g.*, estrogens, or synthetic estrogen such as diethylstilbestrol) and those that possess no hormonal properties (*e.g.*, flutamide). Cyproterone acetate, spironolactone, and Leuprolide are still other examples of antiandrogens or antiandrogen-like agents used in the treatment of prostate disorders.

The androgens

In males there is no process comparable to ovulation and no cyclic release of gonadotropins (hormones that stimulate the gonads, or testes). There is, therefore, no need to suppress the release of gonadotropins by anterior pituitary-hypothalamic axis. Alteration of the amount of pituitary gonadotropins released in the male results largely from the undesirable side effects of various antihypertensive medicines, tranquilizers, and morphine or morphine-like substances. Ultimately such alteration may manifest itself as sterility, impotence, or loss of libido.

The male gonad also does not represent a purposeful target for pharmacologic agents. The testes are, however, affected adversely by the side effects of certain drugs (*e.g.*, anticancer agents) or by exposure to certain occupational or environmental hazards. The most vulnerable type of cells in the testes are the germ cells, which are involved in the process of sperm maturation (spermatogenesis). Immature germ cells (spermatogonia) seem to be the most susceptible to damage by chemicals.

Gossypol, an extract obtained from cottonseed oil, is used as a male oral contraceptive in China. While it has had only limited success, gossypol is an example of a gonadotoxin that cannot inhibit mitotic activity. It produces testes with only Sertoli cells, an action similar to that caused by so-called radiomimetic drugs (*e.g.*, busulfan). (J.A.T.)

KIDNEY PHARMACOLOGY

The kidney is primarily concerned with maintaining the volume and composition of body fluids. It nonselectively filters blood, under pressure, in millions of small units called glomeruli. Large molecules (such as proteins) and cells (such as red blood cells) do not normally pass through the filter into the urine. The filter differentiates only by size, so that useful substances (such as glucose) are filtered out as well as waste products (such as urea, the end-product of nitrogen metabolism). The kidney compensates for this by reabsorbing essential substances and water through the walls of fine tubules, or nephrons, which collect together to deliver their contents into the ureter and then to the bladder, from which urine can be voided. In humans, one litre of filtrate is formed in eight minutes, yet 99 percent of this volume is normally reabsorbed, unless there has been excess fluid intake.

All body fluids have approximately the same strength or tonicity, otherwise considerable osmotic pressures would develop between different compartments. In edema there is excess body fluid with dissolved solutes. When these solutes are absorbed through the walls of the nephrons, after filtration by the glomeruli, an obligatory movement of water, driven by osmotic forces, prevents the body from eliminating excess fluid. By preventing reabsorption of solutes across the walls of the nephrons, both excess solutes and water pass into the bladder. The major use of diuretics is to rid the body of edema fluid that builds up in disease states. Different solutes are moved across the

walls of the nephron by different mechanisms. Diuretics increase the production of urine by interfering with the mechanisms of solute transport.

Regions of the nephron

The nephron can be divided into distinct regions in which the absorptive processes are different: the proximal tubule, leading directly from the glomerulus; the loop of Henle; the distal tubule, leading away from the loop; and the collecting duct. The majority of useful solutes and water are reabsorbed in the proximal tubule, while selective absorption, regulation, and fine tuning to maintain the composition of body fluids in the correct ranges take place in the remaining regions.

Proximal tubule. Carbonic anhydrase inhibitors, such as acetazolamide, dichlorphenamide, and methazolamide, depress the reabsorption of sodium bicarbonate in the proximal tubule by inhibiting an enzyme, carbonic anhydrase, which is involved in the reasborption of bicarbonate. Urine formation is increased. The urine, which is rich in sodium bicarbonate and is alkaline, also has an increased concentration of potassium ions, which can lead to a serious loss of potassium from the body.

The loop of Henle. Diuretics that act in the loop of Henle produce a rapid peak in the excretion of urine (diuresis), which then wanes as the drugs are excreted and because of the compensatory factors due to fluid loss. These diuretics clear sodium chloride (salt) from the body and interfere indirectly with the mechanisms by which water is reabsorbed from the collecting duct. Consequently, large volumes of dilute urine containing sodium, potassium, and chloride ions are formed. The loop diuretics are often also called "high-ceiling diuretics" because they can produce an extra level of diuresis over and above the maximum produced by other classes of diuretic drugs. Examples of this class are furosemide, ethacrynic acid, piretanide, and bumetanide.

Distal tubule. The thiazide class of diuretics interferes with salt reabsorption in the first part of the distal tubule. A mild diuresis results in which sodium, potassium, and chloride ions are eliminated in the urine. The thiazides are widely used in the treatment of hypertension. Examples are chlorothiazide, hydrochlorothiazide, and hydroflumethiazide. Chemically, they are related to the carbonic anhydrase inhibitors.

Role of aldosterone

The adrenal gland releases a hormone, aldosterone, which promotes sodium absorption in the latter part of the distal tubule. Its function is to increase sodium retention in sodium-depleted states. Aldosterone levels, however, may be abnormally high in hyperaldosteronism and in hypertension. Drugs such as spironolactone act as antagonists of aldosterone and compete with it for its site of action in the distal tubule. As with most antagonists, spironolactone has no direct action of its own but simply prevents the action of the hormone, thereby correcting the excess sodium reabsorption.

In the latter part of the distal tubule there are mechanisms that exchange one ion for another; for example, sodium is exchanged for potassium and sodium is exchanged for hydrogen. Sodium is absorbed across the tubule wall while potassium and hydrogen are added to the urine. Thus diuretics such as the thiazides, loop diuretics, and carbonic anhydrase inhibitors, which prevent sodium absorption in the early parts of the nephron, cause an unusually large sodium load to be delivered to the distal tubule. There sodium may be exchanged for other ions, especially potassium, and reabsorbed from the urine. The result is that the body loses a large amount of potassium ions, which is serious if the loss exceeds the capacity of the diet to restore it. Potassium depletion leads to failure of neuromuscular function and to abnormalities of the heart, among other serious effects. The potassium-sparing diuretics amiloride and triamterene block the exchange processes in the distal tubule, and thus prevent potassium loss. Sometimes a mixture of diuretics is used in which a thiazide is taken together with a potassium-sparing diuretic to prevent excess potassium loss. In other instances, the potassium loss may be made up by taking oral potassium supplements in the form of potassium chloride.

Properties of osmotic diuretics

Osmotic diuretics (*e.g.*, mannitol) are substances that have a low molecular weight and are filtered through the glomerulus. They limit the reabsorption of water in the tubule. Osmotic diuretics cannot be reabsorbed from the urine and so they set up a situation of nonequilibrium across the tubule membrane. In order to maintain normal osmotic pressure, water is moved across the membrane, increasing the volume of urine.

In some situations it is desirable to change the acidity or alkalinity of the urine, usually to promote the loss of toxic substances from the body. Urine may be made more alkaline by giving sodium bicarbonate or citrate salts. It may be made more acid by giving ammonium chloride.

(A.W.C.)

DERMATOLOGICAL PHARMACOLOGY

The skin consists of layers called the epidermis and the dermis and of certain appendages such as sweat glands, sebaceous glands (which secrete an oily substance), hair, and nails. There also exists a subcutaneous layer beneath the dermis. The outermost layer of the epidermis is termed the stratum corneum. It consists principally of dead epithelial cells that are filled with a protein, keratin, which waterproofs and toughens the skin. Underlying the stratum corneum are layers comprising granular spinous cells, keratinocytes, melanocytes, and Langhan's cells. The dermis, which is below the epidermis, comprises connective tissue and a number of different cell types; it maintains and nourishes the epidermis through its network of capillaries and lymphatic vessels. Sweat glands and hair follicles, which originate in the dermis and penetrate the stratum corneum of the epidermis, represent a potential route of penetration by drugs or chemicals. The subcutaneous layer is the innermost layer and is composed of loose connective tissue and many fat cells. It provides some degree of insulation and is a location for food storage and the site for subcutaneous injection.

Few chemicals or drugs are absorbed rapidly from intact skin. In fact, the skin effectively retards the diffusion and evaporation even of water except through the sweat glands. There are, however, a few notable exceptions (*e.g.*, certain types of nerve gases, as well as insecticides, scopolamine, and nitroglycerin), and instances where a penetration enhancer (*e.g.*, dimethyl sulfoxide) serves as a vehicle for the drug.

Several factors affect the transport of drugs through the skin (percutaneous) once they are applied topically. The absorption of drugs through the skin is enhanced if the drug is highly soluble in the fats (lipids) of the subcutaneous layer. The addition of water (hydration) to the stratum corneum greatly enhances the percutaneous transport of corticosteroids (anti-inflammatory steroids) and certain other topically applied agents. Hydration can be effected by wrapping the appropriate part of the body with plastic film, thereby facilitating dermal absorption. If the epithelial layer has been removed (denuded) by abrasion or burns, or if it has been affected by a disease, penetration of the drug may proceed more rapidly. A drug will be distributed (partitioned) between the solvent and the lipids of the skin according to the solubility of the solvent in water or lipids. Topical absorption of drugs is facilitated when they are dissolved in solvents that are soluble in both water and lipids. Highly water-soluble, polar molecules, which have a lesser tendency to solubility in lipids, essentially cannot be absorbed percutaneously. Thus, a drug penetrates the skin at a rate determined primarily by its tendency to dissolve in water, or lipids, or both.

Topically applied drugs. Topical application of drugs provides a direct, localized effect on a specific area of the skin. When drugs are applied topically to the skin, they may be dissolved in a variety of vehicles or formulations, ranging from simple solutions to greasy ointments. The particular type of dermal formulation used (powder, ointment, etc.) depends, in part, on the type of skin lesion or disease process.

Therapeutic effects of topical application of drugs

Topically applied medications can relieve itching, exert a constricting or astringent action on the pores, or dissolve or remove the epidermal layers. Other pharmacologic effects from topically applied drugs include antibacterial, anti-inflammatory, antifungal, and antiparasitic actions. Analgesic balms (*e.g.*, wintergreen oil or methyl salicy-

late) have been used topically to relieve minor muscle aches and pains.

Steroids. Corticosteroids (anti-inflammatory steroids) have been used for many years to treat dermatologic disorders. The percutaneous absorption of topically applied corticosteroids is facilitated by encasing the afflicted area with a plastic film (*i.e.*, hydration). Triamcinolone, fluocinolone, dexamethasone, methylprednisolone, and hydrocortisone are examples of synthetic corticosteroids that can be applied topically in ointments, creams, or lotions. Prolonged or excessive use of corticosteroids can lead to systemic levels that produce undesirable side effects, such as salt retention or suppression of the function of the pituitary and adrenal glands.

Anticancer agents. Certain anticancer (cytotoxic) agents or immunosuppressant drugs are applied transdermally to skin disorders, including some skin tumours. An example of such an anticancer agent is 5-fluorouracil.

Photosensitizing. The skin can be affected by other means, including sunscreens, photosensitizing drugs, and pigmenting agents (psoralens). Sunscreens, which act as barriers to sunlight by blocking, scattering, or otherwise reflecting the light, include such agents as para-aminobenzoic acid. Other chemicals (*e.g.*, coal tar) act in conjunction with sunlight on the skin to achieve a high sensitivity to sunlight (photosensitization). Drugs capable of causing photosensitization generally exert their effects following the absorption of light energy. For example, the topical or systemic administration of methoxsalen or trioxsalen prior to the exposure to the ultraviolet radiation of the Sun augments the production of melanin pigment in the skin. These and other psoralens have been used in the treatment of the skin disorder vitiligo in an effort to repigment the whitish patches that commonly occur on the hands and face.

Transdermally applied drugs. The transdermal application of drugs provides an alternate method for applying drugs to achieve a systemic, rather than local, effect. The administration of a drug through the skin not only minimizes the metabolism of the drug before it reaches the rest of the body but also eliminates the high and low blood levels associated with oral administration. A major limitation of transdermal drug administration is that only a small amount of drug can be given through the skin.

Systemic effect of transdermal application

Transdermal drug administration makes use of a variety of structures from which the drug is distributed. The rate of drug release is determined by the properties of the synthetic membrane of the vehicle and the difference in drug concentration across the membrane. To ensure that the drug delivery rate remains constant, the skin must be capable of removing the drug at a rate faster than it is released from the device. Because the anatomical site can influence this rate, testing for the most suitable areas is done for each drug. Examples of transdermal drugs are nitroglycerin, in impregnated disks applied to the upper chest or upper arm, and scopolamine (a drug used to treat motion sickness and nausea), applied in a polymer device behind the ear.

Mucous membranes. Drugs may be applied to mucous membranes, including those of the conjunctiva, mouth, nasopharynx, vagina, colon, rectum, urethra, and bladder. They may either exert a local action or be absorbed into the bloodstream to act elsewhere. Examples include nitroglycerin, which is absorbed from under the tongue (sublingually) to act on the heart and relieve anginal pain, and trifluoperazine, which is a tranquilizer sometimes taken in suppositories. Nasal insufflation, or inhalation, involves the local application of a drug to the mucous membranes of the nose to achieve a systemic action. This represents an effective delivery route of antidiuretic hormone and its analogues in the treatment of diabetes insipidus. Relatively unsuccessful efforts have been made to get hormones of larger molecular weight, such as insulin or growth hormone, to penetrate the mucous membranes of the nasal cavity, thereby avoiding the need to inject such hormones. Although certain medications can be applied successfully to mucous membranes, the topical application of drugs to the skin represents a more widespread and important therapeutic method of administration.

Antibiotics. Although certain antibiotics are used topically, their use should be restricted to the most superficial skin infections. Antibiotics are more often administered systemically. The tetracyclines have been used topically for the treatment of acne. Skin disorders caused by fungi can be treated with either antibiotics or antifungal drugs.

ENDOCRINE PHARMACOLOGY

Control of most body functions is achieved by the nervous system and the endocrine system, which constitute the two main communication systems of the body. They function in a closely coordinated way, each being dependent on the other for its proper operation; the total behaviour of the organism is integrated by a constant traffic of both neural and hormonal signals, which are received and responded to by appropriate tissues. The activities of the central nervous system and of the endocrine glands are themselves dependent on feedback control through neural and hormonal stimuli. This control is related to the toxicity of hormones when used therapeutically because prolonged use of certain hormones or their analogues in this way may quell, sometimes irreversibly, the appropriate gland's output of endogenous hormone.

Coordinated control of body functions

The natural hormones belong to only a few chemical classes. Most are polypeptides, some are derivatives of amino acids (epinephrine, norepinephrine, dopamine, or thyroid hormones), and some are steroids (the sex hormones and the hormones of the adrenal cortex). Polypeptide and amino acid hormones bring about their effects by acting on cell membrane receptors that are specifically sensitive to their action. Steroid hormones penetrate the cell membrane and interact with receptors on specific binding proteins, which then act on the cell nucleus to modify protein synthesis. The techniques of recombinant DNA technology have begun to provide improved methods for obtaining large amounts of scarce human hormones in pure form.

The functions of hormones fall into three general categories: (1) morphogenesis, which is a process that uses hormones to regulate the growth, differentiation, and maturation of the organism (*e.g.*, the development of secondary sex characteristics under the influence of ovarian or testicular hormones); (2) homeostasis, or metabolic regulation, in which hormones are used to maintain a dynamic equilibrium of the components of the body, such as fats, carbohydrates, proteins, electrolytes, and water; and (3) functional integration, whereby hormones regulate or reinforce functions of the nervous system and patterns of behaviour (*e.g.*, the influence of sex hormones on sexual activity and maternal behaviour).

The endocrine system comprises the anterior and posterior lobes of the pituitary gland, the adrenal gland, the pancreas, the gonads (ovaries and testes), and the thyroid and the parathyroid glands. Several of the endocrine glands (thyroid, adrenal cortex, ovaries, and testes) are under the control of the hormones of the anterior lobe of the pituitary gland. The hormones that are released to control the actions of other hormones are called trophic hormones. The release of trophic hormones is under the control of neurons of the hypothalamus, and it is mainly at this level that integration of the activities of the nervous and endocrine systems takes place.

Trophic hormones

The therapeutic use of hormones is concerned primarily with replacement therapy in deficiency states (*e.g.*, deficiency of glucocorticoids in Addison's disease). Hormones and their analogues and antagonists, however, can be used for a variety of additional purposes—*e.g.*, topical corticosteroids and oral contraceptives.

Anterior pituitary gland. The pituitary gland (also called the hypophysis) is situated at the base of the brain. The gland itself is composed of three distinct lobes: the anterior lobe (also called the adenohypophysis), the posterior lobe (also called the neurohypophysis), and the intermediate lobe (or pars intermedia). The pituitary gland is connected by a bridge, the pituitary stalk, through which it receives its blood supply and many neurohumoral and hormonal signals from the region of the brain known as the hypothalamus. Neurohumours are chemical signals produced by nerve cells, and hormones are produced by

endocrine glands; both act in different ways to affect the endocrine system. Hormones emanating from the hypothalamus, called hypothalamic-releasing hormones, affect the secretion or release of hormones stored in the anterior lobe of the pituitary. For each anterior pituitary hormone there is an appropriate corresponding hypothalamic-releasing hormone. There are six important trophic hormones of the mammalian anterior pituitary gland: growth hormone (GH, also called somatotrophin); prolactin; thyrotropin (thyroid-stimulating hormones, or TSH); adrenocorticotropin (adrenocorticotrophic hormone, or ACTH); luteinizing hormone (LH); and follicle-stimulating hormone (FSH).

Growth hormone. As its name implies, growth hormone stimulates the growth of cells in the body. It does not act on a specific group of cells or organs but rather on all of the cells of the body to promote their growth and proliferation. Growth hormone is a protein hormone whose molecular structure consists of a 191-amino-acid sequence. It stimulates bone growth; hence, it plays an important role in the growing child. Pituitary tumours can sometimes result in oversecretion of GH, leading to gigantism or acromegaly. In the United Kingdom, drug treatment for pituitary tumours is carried out with bromocriptine, a substance that resembles dopamine in its actions. Bromocriptine decreases the overproduction of growth hormone by the tumour cells. The consequence of growth hormone deficiency in children is dwarfism, and it is treated by replacement therapy with human growth hormone produced by recombinant DNA technology.

Effects of pituitary tumours

Prolactin. Prolactin, along with other hormones (*e.g.*, oxytocin), acts on cells of the breast to stimulate growth and enhance the secretion of milk (lactation). Prolactin mediates these hormonal actions through receptors that are located within the mammary glands. Inappropriate or excessive secretion of prolactin may be suppressed by treatment with bromocriptine.

Thyrotropin. Thyrotropin (thyroid-stimulating hormone, or TSH) is secreted by the anterior lobe of the pituitary gland upon the command of thyrotropin-releasing hormone (TRH). Through receptors located in the thyroid gland, TSH stimulates the biosynthesis of a thyroid hormone, thyroxine, and other iodine-containing precursors. There is feedback among TRH, TSH, and thyroxine: if TSH causes the thyroid gland to manufacture too much thyroxine, then thyroxine can travel to the pituitary gland and act on receptors that slow down the secretion of TSH and hence TRH. This negative feedback by thyroxine contributes to the body's ability to maintain appropriate levels of the hormones.

Adrenocorticotropin. Adrenocorticotropin (ACTH), a peptide chain of 39 amino acids, is the smallest of the hormones of the anterior pituitary. Adrenocorticotropin is under the central control of corticotropin-releasing factor (CRF). Adrenocorticotropin stimulates the cortex of the adrenal gland to produce a variety of corticosteroids that affect electrolyte and water balance (mineralocorticoid) or carbohydrate, fat, and protein metabolism (glucocorticoids). The principal hormonal action of ACTH is to stimulate steroid biosynthesis, especially cortisol. It is used mainly to verify the diagnosis of adrenal insufficiency (diminished glandular output), but occasionally it is used in nonendocrine disorders that show some response to glucocorticoids (*e.g.*, multiple sclerosis). Tetracosactrin is the polypeptide consisting of the first 24 amino acids of ACTH. It is often used in preference to ACTH because it produces fewer side effects.

Luteinizing hormone. Luteinizing hormone (LH) is one of the two anterior pituitary hormones collectively referred to as gonadotropins (hormones that regulate the functions of the gonads). The other gonadotropin is follicle-stimulating hormone. While both hormones have specific physiologic actions, they often act in concert to moderate the reproductive processes. In females, LH induces ovulation and maintains secretory functions within the uterus. In males, LH acts to stimulate the secretion of male sex steroids (androgens) by specialized cells in the testes (interstitial cells, or Leydig cells). In females, the pituitary secretion of LH is cyclic and along with other hormones is responsible for the menstrual cycle. In males, other than some minor fluctuations in hormonal levels due to daily variations, the pituitary secretion of LH is steady.

Follicle-stimulating hormone. Like LH, follicle-stimulating hormone (FSH) is a glycoprotein secreted by the anterior pituitary gland. In females, FSH stimulates the development of ovarian follicles as well as the biosynthesis of female sex steroids (estrogens). The rupture of the follicle, thought to be assisted by LH, gives rise to the release of an ovum, or egg. The process is referred to as ovulation. It is necessary that FSH prime the follicles prior to the actual rupturing process caused by LH. Although LH is known as the ovulatory hormone, it could not accomplish this physiologic function without the prior actions of FSH. In males, FSH stimulates two types of specialized cells also found in the testes: primordial germ cells (gametes) and Sertoli's cells (also called sustentacular cells). The maturation of germ cells (spermatogonia) is stimulated by FSH; the process is termed spermatogenesis. Follicle-stimulating hormone also stimulates the secretion of certain proteins in the testes.

Role of FSH in ovulation

Gonadotropins (LH and FSH), extracted from the urine of postmenopausal women, and chorionic gonadotropins (produced by the placenta), extracted from the urine of pregnant women, are used to promote ovulation in infertile women in whom the pituitary is primarily the cause of infertility. Chorionic gonadotropin is sometimes used in the condition called cryptorchidism, in which the testes failed to descend into the scrotum in childhood.

Posterior pituitary gland. The posterior pituitary gland secretes two hormones, oxytocin and vasopressin. Vasopressin is also called antidiuretic hormone (ADH) since one of its physiologic actions is exerted on the kidney, leading to a reduction in urinary output. Oxytocin and ADH are octapeptides whose secretion is modulated by secretory activities of nerve cells (neurosecretion) located in specialized regions of the hypothalamus.

Vasopressin. A disease known as diabetes insipidus is characterized by the excessive production of urine with a high concentration of water, which is the result of the failure of the kidney tubules to reabsorb the proper amount of water. A common cause of diabetes insipidus is the inadequate production of vasopressin by the pituitary. The condition may be treated by replacement of vasopressin or by the use of its synthetic analogue desmopressin. Vasopressin also plays a role as a neurotransmitter in the brain, and there is some evidence that it is involved in memory storage and in mood.

Oxytocin. Oxytocin exerts its hormonal effects on the uterus and the mammary gland. Oxytocin increases the frequency and strength of the concentrations of the muscles of the uterus, particularly during labour. Oxytocin facilitates the birth process by aiding the expulsion of the fetus and the placenta. This hormone also facilitates lactation by stimulating the contraction of myoepithelial cells surrounding the ductal system of the mammary glands. Oxytocin may be used to induce labour, especially when gestation approaches or exceeds 40 weeks.

Adrenal gland. The adrenal gland is a compound organ situated on top of the kidney. It consists of an outer cortex (adrenal cortex) and an inner medulla (adrenal medulla). The hormones secreted from the cortex are steroids, generally classified as mineralocorticoids and glucocorticoids. Those substances emanating from the medulla are amines such as epinephrine and norepinephrine. Epinephrine and norepinephrine are catecholamines, which are present in several cell types in the body and serve as neurotransmitters both in the brain and in the autonomic nervous system. Thus, the adrenal medulla functions with the sympathetic nervous system.

Steroids and amines

The adrenal cortex secretes glucocorticoids (*e.g.*, cortisol) and mineralocorticoids (*e.g.*, aldosterone, which causes sodium retention and potassium excretion by the kidney). Glucocorticoids together with mineralocorticoids are used in replacement therapy in acute or chronic adrenal insufficiency (Addison's disease).

Glucocorticoids, including a range of synthetic analogues (*e.g.*, prednisolone, triamcinolone, and dexamethasone), are used as anti-inflammatory and immunosuppressant

agents. As anti-inflammatory agents they are used topically and in bronchial asthma. Glucocorticoids stimulate the synthesis of a glycoprotein called macrocortin that inhibits the enzyme phospholipase A_2. Phospholipase A_2 plays an essential role in the synthesis of prostaglandins and leukotrienes; its inhibition by macrocortin underlies the anti-inflammatory effects of glucocorticoids.

Glucocorticoids also have an antivitamin D action and accordingly are used in hypercalcemia (excess concentration of calcium in the blood) associated with sarcoidosis or vitamin D overdosage. They are used in some life-threatening diseases, including certain cancers.

Thyroid and parathyroid glands. Anatomically, there is close proximity between the thyroid and the parathyroid gland, yet they have very different hormonal functions and different mechanisms of stimulation. Secretion of thyroxine and triiodothyronine from the thyroid gland is stimulated by TSH, whereas secretion of parathyroid hormone (PTH) from the parathyroid gland and calcitonin from the thyroid gland are modulated by circulating levels of calcium and phosphate in the blood.

Parathyroid hormone. Parathyroid hormone (PTH) is a single-chain amino acid molecule secreted by the chief cells of the parathyroid gland. The major regulator of PTH is the level of ionized calcium in the blood. Receptors for PTH are located in bones and in the kidney. The primary function of PTH is to prevent hypocalcemia (lowered blood calcium levels) by stimulating the release of calcium from bone and by increasing the reabsorption of calcium in the kidney. Tetany, often characterized by muscle twitching, spasms, and even convulsions, is the result of precariously low levels of blood calcium. Tetany resulting from hypocalcemia can be treated by administering calcium gluconate and vitamin D.

Calcitonin. Calcitonin is synthesized in the thyroid, the parathyroid, and the thymus glands. It is capable of counteracting calcium-releasing effects of PTH because calcitonin reduces blood calcium levels by increasing its deposition in bone and enhancing its excretion in the urine.

Thyroxine and triiodothyronine. Thyroxine (T_4) and triiodothyronine (T_3) are the major iodine-containing hormones synthesized in the thyroid gland, and their synthesis is stimulated by pituitary TSH. Iodine is also required in their manufacture. The biochemical actions of the thyroid hormones are complex, although their most evident effect is stimulation of cellular metabolism. Both T_4 and T_3 increase the basal metabolic rate (measure of the minimum number of calories needed to sustain only the activities essential to life) and are calorigenic (energy-producing). A diet deficient in iodide can lead to the formation of a goitre (an enlargement of the thyroid); iodized table salt can prevent this abnormality. Enlargement of the thyroid gland often is due to the unchecked secretion of TSH when there is too little iodide to provide for the manufacture of T_4 or T_3, which are the hormones that normally reduce the secretion of the pituitary trophic hormone TSH. Excessive thyroid hormone production (hyperthyroidism) in adults is commonly referred to as thyrotoxicosis; a common type in young adults is exophthalmic goitre (Graves' disease). In this disease there is increased activity of thyroid hormones as a consequence of an immunoglobulin called long-acting thyroid stimulator (LATS) that is produced in lymphoid tissue. The circulating level of TSH is low because of negative feedback, but LATS is not susceptible to negative feedback. In older patients, thyroid cancers are more commonly the cause of hyperthyroidism. Treatments include surgery; the use of radioactive iodine, which is taken up by the thyroid and then irradiates it; and antithyroid drugs such as carbimazole.

Importance of iodine

Thyroid deficiency in newborns can lead to cretinism, which is characterized by mental retardation. In adults, hypothyroidism leads to the condition called myxedema. Thyroxine is used to treat hypothyroid conditions in both infants and adults.

Pancreas. The pancreas has both an endocrine (secretion of insulin and glucagon) and a digestive function. A deficiency in the pancreatic secretion of insulin leads to diabetes mellitus ("sugar diabetes"). One of insulin's important physiological actions is to control blood sugar (glucose) levels. This carbohydrate is an important nutrient for cellular metabolism, and the cell must receive neither too little nor too much. Diabetes mellitus is a complex metabolic disease that is caused both by genetic factors (juvenile-type diabetes, also called type I diabetes) and by the aging process (maturity-onset, or type II, diabetes) in the pancreatic cells responsible for secreting the protein hormone insulin. The islets of Langerhans in the pancreas contain a specialized type of cell called the *beta*, or B, cell, which secretes insulin. A lack or absence of B cells, among other disease factors, can lead to diabetes mellitus. Once secreted by the B cell into the bloodstream, insulin can affect a number of important metabolic actions on cells located in the muscles, liver, and other sites. Normally, insulin secretion is increased following the ingestion of carbohydrates; the liver is responsible for eventually curtailing the biologic actions of insulin. Insulin has a number of important metabolic actions upon both fat and protein as well.

Insulin

Because insulin is a polypeptide it cannot be administered orally since proteolytic enzymes present in the stomach and gastrointestinal tract destroy its physiological properties. Insulin must be injected parenterally so that it enters the bloodstream and eventually reaches the body's cells. Insulin can be obtained from the pancreas of domestic animals, and the hormone now can be made by bacteria following recombinant DNA techniques. An overdose of insulin can produce hypoglycemia (low blood sugar), which may lead to convulsions. Several other hormones (*e.g.*, growth hormone and glucocorticoids) can antagonize insulin's actions.

Maturity-onset diabetes often may be treated with oral hypoglycemic drugs instead of with insulin. These drugs are of two types. In the United States, only the sulfonylureas (*e.g.*, tolbutamide) are used, which increase the release of endogenous insulin and increase the number of insulin receptors. In the United Kingdom, the biguanides (*e.g.*, metformin) are used to lower blood sugar by uncertain mechanisms that may include decreased absorption, decreased synthesis from protein, increased glucose utilization, and decreased appetite.

Another set of specialized cells located in the pancreas secrete a protein hormone called glucagon. Glucagon can stimulate the breakdown of liver glycogen, leading to a release of glucose into the bloodstream. Thus, under certain instances, glucagon can counteract the actions of insulin. The physiological or pathological significance of the antagonistic relationship between insulin and glucagon is not fully understood. Unlike insulin, there is no known human disease associated with either increased or decreased physiological levels of glucagon. (J.A.T.)

HISTAMINE AND ANTIHISTAMINES

Histamine is a chemical messenger involved in a number of complex biologic actions. It is widely distributed in the plant and animal kingdoms. In humans it occurs mainly in an inactive bound form in most body tissues. When released, it interacts with specific macromolecules (histamine receptors) on the cell surface or within a target cell to elicit changes in many different bodily functions. Histamine is a small, polar, organic molecule of low molecular weight, which comprises an imidazole ring and an ethylamine side chain; it is water soluble and is a base.

Antihistamines are a group of synthetic drugs that can inhibit various actions of histamine. They have some chemical resemblance to histamine and act as antagonists by competing with histamine for occupation of its receptor sites, thereby preventing histamine from eliciting its usual responses. They are helpful therapeutically in preventing rather than in reversing histamine actions.

Antagonistic properties of antihistamines

The chief sites of histamine in the body are the mast cells of connective tissue and their circulating counterparts in the blood, the basophils. These cells synthesize histamine by the action of an enzyme that removes the carboxyl group from the amino acid L-histidine. Histamine is then stored in many tissues of the body. If the histamine is released, more of it is slowly synthesized at these sites. There are, however, organs in which the histamine-

containing cells have not been identified. Some tissues have a high capacity for synthesizing histamine without storing it. Cells in regenerating or rapidly growing tissues also produce large amounts of histamine, which is continuously released.

Free histamine produces many powerful and varied biologic actions. It appears to act on specific receptors in the membranes of cell surfaces. These receptors have not been isolated or identified, but their presence is inferred by the use of synthetic drugs. Three types of pharmacological histamine receptor have been described, and they are designated as H_1, H_2, and H_3.

Histamine stimulates many smooth muscles to contract, such as those in the gastrointestinal tract, the uterus, and the bronchi. In some smooth muscle, however, it causes relaxation, notably that of fine blood vessels, whose dilation may produce a pronounced fall in blood pressure. Histamine also increases the permeability of the walls of the capillaries so that more of the constituents of the plasma can escape into the tissue spaces, leading to an increase in the flow of lymph and its protein content and to the formation of edema. These effects are manifested in the redness and weal associated with histamine release, as may occur after a scratch from a blunt instrument or a nettle sting. There are striking differences, however, in the response of different animal species to histamine. For example, the rat is relatively resistant whereas the guinea pig and man are very sensitive.

Location of histamine

Histamine appears to have a physiological role in the body's defenses against a hostile environment. Histamine is found in the body's surfaces: in the skin, in the respiratory membrane and adjacent tissue, and in the lining of the alimentary, or digestive, canal. Histamine may be released from tissue mast cells and blood basophils when the body is subjected to mechanical damage, burning, infection, or some drugs. Histamine assists the body in removing the products of cell damage from inflammation. In humans, the most common circumstance in which histamine is liberated is as a result of the antibodies produced by foreign proteins. Under extreme circumstances, the effects of histamine become pathological, leading to exaggerated responses with distressing results, as may occur in some allergic conditions.

Synthetic drugs known as antihistamines (*e.g.,* mepyramine, diphenhydramine, and chlorpheniramine) have been available since 1945, although subsequently they have been designated more precisely as H_1-receptor histamine antagonists or H_1-receptor blockers. The H_1 antihistamines are used to suppress or alleviate the symptoms in various allergic conditions; they do so by competing with the released histamine for occupation of its H_1 receptors. They may be effective in the treatment of seasonal hay fever (seasonal rhinitis and conjuctivitis) to relieve sneezing, rhinorrhea, and itching of eyes, nose, and throat. In general, the H_1 antihistamines tend to be more successful in controlling acute than chronic conditions; thus, they are most useful at the beginning of the hay-fever season when the allergens are present in low concentration, but in perennial vasomotor rhinitis (nonseasonal, nonallergic inflammation of the mucous membranes of the nose brought on by environmental or emotional stimuli) they are only of limited value. They are not usually effective in asthma, indicating that in this condition histamine is not the main agent producing the symptoms. Certain allergic skin reactions respond favourably to H_1 antihistamines, which are particularly effective for treatment of acute urticarial rashes (or weals) of the skin and the itch and swelling of insect bites.

The H_1 antihistamines are relatively free from serious side effects, and the margin between therapeutic and toxic dose is generally large. Less serious side effects are common, the most notable being drowsiness. New H_1 antihistamines, however, are relatively free of this side effect. The action of some H_1 antihistamines on the central nervous system has been put to advantage in the prevention and treatment of motion sickness and nausea and of mild insomnia. The main antihistamines used in the treatment of motion sickness include cinnarizine, cyclizine, dimenhydrinate, mepyramine, and promethazine. Because they also possess sedative action (especially dimenhydrinate and promethazine), they may impair a person's performance while driving and enhance the effects of alcohol and other depressant drugs that act on the central nervous system. Antihistamines bind strongly to H_1 receptors in the brain, but it is not known whether this action is responsible for their beneficial effect in motion sickness. Some also bind to mascarinic receptors in the brain, and this action may contribute to their beneficial effect.

Histamine's role in the stomach

Histamine has a physiological role in regulating the secretion of acid in the stomach, where it stimulates the parietal cells to produce hydrochloric acid. This is probably protective, since the acid controls the local bacterial population. A pathological situation can arise, however, as in the formation of gastric or duodenal ulcers. In the 1970s a new class of synthetic drugs was invented that blocked the action of histamine at its H_2 receptors. These drugs were shown to be extremely effective in antagonizing the action of histamine in stimulating acid secretion and in blocking other stimulants of acid secretion, including the hormone gastrin and food. The H_2-receptor antagonist drugs, such as cimetidine and ranitidine, rapidly established a place in the treatment of conditions involving the hypersecretion of gastric acid, and they revolutionized the treatment of duodenal ulcers and the Zollinger-Ellison syndrome. Their safety record has been excellent, and they provide a valuable alternative to surgery.

Although the H_2-receptor antagonists drugs also block the effects of histamine on H_2 receptors at other sites (notably in the heart and blood vessels and on parts of the immune system), this has not proved to be a problem during therapeutic use. Histamine is not normally involved in other homeostatic mechanisms and even if it is, it affects systems that are also subject to control by many other messenger substances. There are circumstances in which it may be advantageous to administer H_1- and H_2-receptor antagonist drugs as the same time; *e.g.,* in treating the fall in blood pressure in anaphylactic shock (an exaggerated allergic reaction), involving both types of receptors.

Histamine has other actions in which its role is less well understood. It can stimulate the heart to beat faster or to increase its force of contraction. It can modify the responsiveness of various types of lymphocytes in the blood during the course of immunological reactions, and it may also affect the movements of specialized cells in the blood. Histamine storage sites and receptors, as well as the biochemical enzymes required for producing and disposing of histamine, are present in the brain; it is probable that histamine has a neurotransmitter role, but its function is unclear. The role of the histamine H_3 receptor is relatively unexplored. It can apparently regulate release of histamine in the brain and may therefore be involved in the transmission of neuronal signals.

Role of histamine as a drug

Histamine has had limited use as a drug. Applied topically, for example, in creams, it has been used to treat muscular pain, such as lumbago and fibrositis, and as a peripheral vasodilator to treat recurrent itching and swelling of toes, fingers, or ears (chilblains). A synthetic analogue that possesses some selectivity toward H_1 receptors is betahistine, which has had some use in preventing Menière's disease (vertigo, deafness, and other vestibular disturbances).

Histamine has also been used as a diagnostic agent. In the diagnosis of pheochromocytoma (a tumour of the adrenal medulla), histamine acts via an H_1 receptor to cause the liberation of norepinephrine and epinephrine from the tumour; this leads to a rise in blood pressure, whereas in a normal subject the blood pressure falls. Histamine acting via its H_2 receptor has been used to diagnose impairment of the acid-producing cells of the stomach; the absence of acid after an injection of histamine indicates that the acid-secreting glands are not functioning, a situation that results in pernicious anemia. A chemical analogue of histamine, betazole, is less potent but more selective as a stimulant of acid secretion. Impromidine is a potent synthetic analogue that is a highly selective stimulant for H_2 receptors.

Released histamine does not last long in the body; it is rapidly inactivated and disappears from the bloodstream within minutes. Its biologic inactivation occurs by one of

two mechanisms: (1) its side chain may lose its amine group (deamination) through oxidation by the enzyme diamine oxidase (histaminase); or (2) it may gain a methyl group (methylation) in the imidazole ring by the enzyme histamine-N-methyltransferase. (C.R.G.)

CHEMOTHERAPY

Chemotherapy, in its broadest sense, refers to the treatment of disease with chemicals. In current usage, however, the term applies primarily to the treatment of infectious diseases and cancer. When used to refer to infectious diseases, the term is antimicrobial chemotherapy. Antimicrobial chemotherapy can be used either for prophylaxis (prevention) or treatment (cure) of disease caused by bacteria, fungi, viruses, protozoa, or helminths. Cancer chemotherapy uses synthetic chemicals and antibiotics that can differentiate to some degree between normal tissue cells and cancer cells. Chemotherapy is used in the treatment of cancer; no therapeutic agents are available for the prevention of cancer. The dramatic progress made in the transplantation of tissue and organs has been due, in part, to the use of chemicals that modify the immune response in recipients of these tissue and organs.

The production and use of penicillin in the early 1940s became the basis for the era of modern antimicrobial chemotherapy. Streptomycin was discovered in 1944, and since then many other antibiotics have been found and put into use.

Modification of the basic structure of drugs

A major discovery following the introduction of antimicrobials to medicine was the finding that their basic structure could be modified chemically to improve their characteristics. The finding of a bacterium that produces the basic structural component responsible for the antimicrobial activity of penicillins and cephalosporins now permits engineering of compounds with vastly improved pharmacokinetics and with activity specific for certain microorganisms.

The discovery and use of antimicrobial agents has not eliminated infectious diseases, but it has dramatically reduced the predominance of many. The use of antimicrobial agents, however, has itself created problems. Some microorganisms have become resistant to drugs, requiring a continuing search for different (and often more expensive) agents. This increase in resistance to drugs has resulted from their widespread and sometimes indiscriminate use. In other cases, the use of antimicrobial agents has caused a change in the microbial ecology of humans and the environment. These resistant bacteria are commonly found in hospitals (nosocomial infections), where they can infect persons whose resistance already is decreased.

Basic concepts. An ideal chemotherapeutic agent is one that is cidal (kills) rather than static (inhibiting growth). It should affect a specific microbe or tissue cell and not affect other microbes or normal cells. It should be one to which the infectious organism or cancer does not become resistant and one that is not allergic or toxic to the host. An ideal chemotherapeutic agent must have pharmacological attributes favourable for its use. Therefore, if it is to affect organisms in the gastrointestinal tract, it must remain in the intestinal tract and not be absorbed or inactivated when given orally. If an oral drug is used to affect organisms in the blood or tissues, then it must be absorbed from the intestinal tract or it must be capable of being given parenterally (by injection). It must be able to penetrate tissues and be maintained for adequate periods of time at the site of the infection or cancer in concentrations sufficient to affect the microorganism or cancer cells.

The factors that affect these conditions are molecular size, ionic charge, rate of metabolism and excretion (half-life), lipid solubility, degree of protein binding, and presence or absence of inflammation in the tissue. The chemotherapeutic agent must be selectively toxic; that is, it should be active against the microorganism or cancer cell but it must not be toxic for the host in the amount administered.

Chemotherapeutic index

None of the chemotherapeutic agents presently in use meets all of these criteria. In fact, a number of compounds that produce significant toxic effects in humans are used because they have a favourable chemotherapeutic index; that is, the amount required for a therapeutic effect is below the amount that causes a toxic effect. The levels of these drugs in the patient must be carefully controlled so as not to exceed toxic levels.

Persons with certain altered organ functions, such as occurs in liver or kidney disease, are often especially susceptible to drug toxicity. Chemotherapeutic agents, however, can be used safely if drug concentrations in blood are measured, the dose adjusted to avoid toxic levels, and organ function or toxicity monitored closely.

Chemotherapeutic agents that are used in the treatment of disease are of three sources: (1) the synthetic chemicals; (2) chemical substances or metabolic products made by microorganisms, a group containing the antibiotics; and (3) plants.

Adverse effects. All chemotherapeutic agents can have adverse effects ranging from relatively harmless to serious and life-threatening, sometimes culminating in death. These effects can be due to direct toxicity; allergic or hypersensitivity reactions; or alterations in the numbers and types of micoorganisms that are the normal flora found in the mouth, intestine, vagina, skin, etc.

Direct toxicities are expressed in a variety of ways, and many of these are associated with the gastrointestinal tract (nausea, vomiting, and diarrhea) and skin rashes. They are usually minor and do not limit the use of the agent. In more extreme cases, the toxicities can result in serious damage to organs such as the kidneys, liver, and eyes and to the nervous system. Some chemotherapeutic agents affect normal red blood cells, which can result in anemia. Allergic or hypersensitivity reactions can range from minor effects such as skin rash and itching to more serious effects that include choking and difficulty in breathing. In some cases, a sudden and severe form of allergy (anaphylaxis) can result in death.

The use of antimicrobial agents, in particular the broad-spectrum agents (see below *Antibacterial drugs*), can result in an alteration in the number and type of microorganisms normally found on the skin and mucosal surfaces. This is due to the inhibitory activity of the antimicrobial agent on sensitive microorganisms found on these tissues. The eradication of some organisms relieves the inhibitory activity they have on each other, thereby allowing the surviving (resistant) organisms to multiply. In some cases, organisms such as yeast that are generally resistant to antibiotics increase to numbers sufficient to invade and infect tissue.

Categorization of antibacterial agents

Antibacterial drugs. Antibacterial agents are categorized as narrow-, broad-, or extended-spectrum agents. Narrow-spectrum agents (*e.g.,* penicillin G) affect primarily gram-positive bacteria. Broad-spectrum antibiotics, such as tetracyclines and chloramphenicol, affect both gram-positive and some gram-negative bacteria. An extended-spectrum antibiotic is one that, as a result of chemical modification, affects additional types of bacteria, usually gram-negative bacteria.

Whether an antimicrobial agent affects a microorganism depends on several factors. The drug must be delivered to a sensitive site in the cell, such as an enzyme that is involved in the synthesis of a cell wall or a protein or enzyme responsible for the synthesis of proteins, nucleic acids, or the cell membrane. Whether the antibiotic enters the cell depends on the ability of the drug to penetrate the outer membrane of the cell, or on the presence or absence of transport systems for the antimicrobial agent, or on the availability of channels in the cell surface. In some cases the microorganism prevents the entry of the antibiotic by producing an enzyme that destroys or modifies the antibiotic by transferring a chemical group. If the antimicrobial agent does not penetrate the organism or is destroyed or modified, or if the organism does not contain a sensitive site, then the microorganism will not be affected; in such a case it is said to be resistant.

A major problem associated with the use of antibacterial drugs is that an organism that originally was sensitive to a given drug can become resistant. For example, bacteria undergo spontaneous mutations; and exposure of these bacteria to an antimicrobial can eradicate sensitive organisms, thereby selecting a population resistant to that drug

and sometimes to related drugs. Bacteria sensitive to antimicrobial agents can become resistant by acquiring from resistant organisms deoxyribonucleic acid (DNA) containing genes coding for resistance (resistance genes). Bacteria sensitive to an antimicrobial can mate (conjugation) with bacteria containing resistance genes, or they can acquire these resistance genes by transduction. In transduction, a bacterial virus (bacteriophage) incorporates resistance genes into its genome by infecting a resistant bacterium. When the bacterial virus infects another bacterium, the phage DNA (containing resistance genes) can be incorporated into that bacterium and confer resistance. Some bacteria may acquire multiple resistance genes simultaneously and become resistant to several antibiotics. This is possible because circular pieces of DNA (plasmids) can, by recombination, acquire several genes, each of which codes for resistance to a different agent. Plasmids containing these multiple resistance genes can transfer to sensitive bacteria and thereby confer multiple resistance. Transfer of genes into the chromosome or into plasmids is facilitated in many cases because the genes are found on transposons, which are sequences of DNA that can excise themselves from plasmids and chromosomes and insert themselves into other plasmids and chromosomes. Bacteria resistant to as many as 10 different antimicrobial agents are known. One of the major problems associated with the transfer of resistance genes is that they can be transferred not only among similar but also to quite different bacteria.

Transposons

Resistance to antimicrobial agents results from (1) decreased permeability of the organism to the drug; (2) deactivation or modification of the drug by an enzyme; (3) modification of the drug receptor or binding site; (4) increased synthesis of an essential metabolite whose production is blocked by the antimicrobial agent; or (5) production of an enzyme that is altered so that it is not inhibited or affected by the drug.

Antibiotics. Antibiotics are substances produced by microorganisms that at low concentrations kill or inhibit other microorganisms. They are produced commonly by soil microorganisms and probably represent a means by which organisms in a complex environment, such as soil, control the growth of competing microorganisms. The microorganisms that produce antibiotics useful in preventing or treating disease include bacteria (*Bacillus* and *Streptomyces*) and fungi (*Penicillium, Cephalosporium,* and *Micromonospora*). Antibiotics can inhibit microbes by inhibiting the synthesis of the cell wall.

Other antibiotics, such as the aminoglycosides, chloramphenicol, erythromycins, and clindamycin, inhibit protein synthesis in bacteria. The basic process by which bacteria and animal cells synthesize proteins is similar, but the proteins involved are different. Those antibiotics that are useful as antibacterial agents (selectively toxic) utilize these differences to bind to or inhibit the function of the proteins of the bacterium, thereby preventing the synthesis of new proteins and new bacterial cells. Antibiotics such as polymyxin B and colistin bind to phospholipids in the cell membrane of the bacterium and interfere with its function as a selective barrier; this allows essential macromolecules in the cell to leak out, resulting in the death of the cell. Because other cells, including human cells, have similar or identical phospholipids, these antibiotics are somewhat toxic. One antibiotic, rifampin, interferes with RNA synthesis in bacteria by binding to a subunit on the bacterial enzyme responsible for duplication of RNA. Since the affinity of rifampin is much stronger for the bacterial enzyme than for the mammalian enzyme, the mammalian cells are unaffected at therapeutic dosages.

Bacteria, unlike animal cells, have a cell wall surrounding a cytoplasmic membrane. Production of the cell wall involves the partial assembly of wall components inside the cell, transport of these structures through the cell membrane to the growing wall, assembly into the wall, and finally cross-linking of the strands of wall material. Antibiotics that inhibit the synthesis of a cell wall have a specific effect on one or another phase. The result is an alteration in the cell wall and in the shape of the organism and the eventual death of the bacterium.

The penicillins and cephalosporins both have a unique structure, a β-lactam ring, that is responsible for their antibacterial activity. The β-lactam ring interacts with proteins in the cell responsible for the final step in the assembly of the cell wall. Thus, the mechanism of action is identical for both antibiotics; however, the basic chemical structure of the penicillins and cephalosporins differs in other respects, resulting in some difference in pharmacokinetics and the spectrum of antimicrobial activity.

The penicillins can be divided into two groups: the naturally occurring penicillins (penicillin G, penicillin V, and benzathine penicillin) and the semisynthetic penicillins. The semisynthetic penicillins are produced by growing the mold *Penicillium* under conditions whereby only the basic molecule (6-aminopenicillanic acid) is produced. By adding certain chemical groups to this molecule, several different semisynthetic penicillins are produced that vary in resistance to degradation by β-lactamase (penicillinase), an enzyme that specifically breaks the β-lactam ring, thereby inactivating the antibiotic. In addition, the antimicrobial spectrum of activity and pharmacological properties of the natural penicillins can be changed and improved by these chemical modifications.

The naturally occurring penicillins are important chemotherapeutic agents. Even after 40 years of use they are still the drugs of choice for treating streptococcal sore throat, tonsillitis, pneumococcal pneumonia, endocarditis caused by some streptococci, syphilis, gonorrhea, meningococcal infections, and infections caused by some anaerobic organisms. Several microorganisms, most notably the staphylococci, developed resistance to the naturally occurring penicillins, which led to the production of the penicillinase-resistant penicillins (methicillin, oxacillin, nafcillin, cloxacillin, and dicloxacillin).

To extend the usefulness of the penicillins to the treatment of infections caused by gram-negative rods, the broad-spectrum penicillins (ampicillin, amoxicillin, carbenicillin, and ticarcillin) were developed. These penicillins are sensitive to penicillinase, but they are useful in treating urinary tract infections caused by gram-negative rods as well as in treating typhoid and enteric fevers.

The extended-spectrum agents (mezlocillin, azlocillin, and piperacillin) are unique in that they have greater activity against gram-negative bacteria, including *Pseudomonas aeruginosa.* They have decreased activity, however, against penicillinase-resistant *Staphylococcus aureus.*

The penicillins are the safest of all antibiotics. The major adverse reaction associated with their use is hypersensitivity, with reactions ranging from a rash to bronchospasm and anaphylaxis. The more serious reactions are uncommon.

The cephalosporins are produced by *Cephalosporium acremonium.* Modification of the basic molecule (7-aminocephalosporanic acid) has resulted in three generations of cephalosporins. The first-generation cephalosporins (cefazolin, cephalothin, and cephapirin) have a range of antimicrobial activity similar to the broad-spectrum penicillins. The second-generation cephalosporins (cefamandole, cefonicid, cefotetan, cefoxitin, and cefuroxime) have greater β-lactamase stability than the earlier cephalosporins, and their antibacterial spectrum has been extended to include greater activity against additional species of gram-negative rods. They have decreased activity, however, against gram-positive bacteria. Like the penicillins, the cephalosporins are relatively nontoxic. Because the structure of the cephalosporins is similar to that of penicillin, hypersensitivity reactions can occur in penicillin-hypersensitive patients.

Generations of cephalosporins

Cycloserine, an antibiotic produced by *Streptomyces orchidaceus,* is a structural analogue of the amino acid D-alanine, and it interferes with enzymes necessary for incorporation of D-alanine into the bacterial cell wall. It is rapidly absorbed from the gastrointestinal tract and penetrates most tissues quite well; high levels are found in urine. It is used in the treatment of tuberculosis and in some urinary tract infections.

Bacitracin is produced by a special strain of *Bacillus subtilis.* Because of its toxicity its use is limited to the topical treatment of skin infections caused by streptococci and staphlococci and for eye and ear infections. Van-

comycin, an antibiotic produced by *Streptomyces orientalis*, is poorly absorbed from the gastrointestinal tract and is usually given by intravenous injection. It is an excellent antibiotic for the treatment of serious staphylococcal infections caused by strains resistant to the various penicillins.

The aminoglycosides (streptomycin; neomycin; paromomycin; kanamycin and its derivative, amikacin; tobramycin; netilmicin; and spectinomycin) are produced by *Streptomyces* species. Gentamicin is produced by the molds *Micromonospora purpurea* and *M. echinospora*. All of the aminoglycosides inhibit protein synthesis, although spectinomycin, which has a different structure, does so by a mechanism different from the other aminoglycosides. The aminoglycosides are poorly absorbed from the gastrointestinal tract, so, with some exceptions, they are given by intramuscular injection. Neomycin is toxic and is used topically. Because it is poorly absorbed from the gastrointestinal tract, paromomycin is used in the treatment of protozoal infections of the intestinal tract.

Streptomycin was the first of the aminoglycosides to be discovered and the second antibiotic used in chemotherapy. One of its more important uses had been as part of the combined therapy for tuberculosis. It still has some use in combination with penicillin for treating infections of heart valves (endocarditis) and with tetracyclines in the treatment of plague, tularemia, and brucellosis.

Kanamycin is used in the treatment of septicemia (blood poisoning), meningitis, and urinary tract infections caused by gram-negative bacteria. Because many organisms are resistant to its effects, however, kanamycin is now being replaced by other drugs. Gentamicin, tobramycin, netilmicin, and amikacin are similar in their range of antimicrobial activity. They are effective against infections caused by staphylococci and gram-negative bacteria, including *Pseudomonas aeruginosa*.

Margin of safety of aminoglycosides

The major problem with the aminoglycosides is that the margin of safety between a toxic and a therapeutic dose is narrow. Nephrotoxicity (harmful to kidney cells) and ototoxicity (harmful to the eighth cranial nerve of the organs of hearing and balance) are frequent, and the risk of these reactions increases with age and with preexisting renal diseases or hearing loss. Spectinomycin does not have the serious toxicity associated with the other aminoglycosides. It is used solely in treating gonorrhea in persons who are hypersensitive to penicillin or in those with gonococcal organisms resistant to penicillin.

Tetracyclines have a common structure but differ from each other by the presence or absence of chloride, methyl, and hydroxyl groups. Although these modifications do not change their broad-spectrum antimicrobial activity, they do affect pharmacological properties such as half-life in serum and protein-binding ability in serum. The tetracyclines all have the same antimicrobial spectrum, although there are some differences in sensitivity of the microorganisms to the various types of tetracyclines. They inhibit protein synthesis in both bacterial and animal cells. Bacteria have a system that allows tetracyclines to be transported into the cell, whereas animal cells do not; animal cells therefore are spared the effects of tetracycline on protein synthesis.

All tetracyclines are absorbed from the gastrointestinal tract after oral administration, and most can be given intravenously or intramuscularly. Because calcium, magnesium, aluminum, and iron form insoluble products with most tetracyclines, they cannot be given simultaneously with substances containing these minerals (*e.g.*, milk). They are the drugs of choice in the treatment of cholera, rickettsial infections, relapsing fever, trachoma (a chronic infection involving the eye), psittacosis (a disease transmitted by certain birds), brucellosis, tularemia, and respiratory infections. Tetracyclines are also used for acne vulgaris. Because not all of the orally administered tetracycline is absorbed from the gastrointestinal tract, the bacterial population of the intestine can become resistant to tetracyclines, resulting in overgrowth (suprainfection) of resistant organisms. Complexes between tetracyclines and calcium can cause staining of teeth and retardation of bone growth in young children or in the newborn if tetracyclines are taken by the mother after the fourth month of pregnancy. Tetracycline can also cause photosensitivity in patients exposed to sunlight.

Chloramphenicol now is synthesized chemically, but originally it was isolated from cultures of the bacterium *Streptomyces venezuelae*. It is administered either orally or parenterally, but since it is readily absorbed from the gastrointestinal tract, parenteral administration is reserved for serious infections. It is a broad-spectrum antibiotic used in the treatment of typhoid fever and for infections caused by microorganisms resistant to penicillin. Because newborns, particularly the premature newborn, cannot metabolize chloramphenicol, high levels accumulate and can cause inadequate oxygenation, the "gray syndrome." The most serious adverse effect is a toxic decrease in bone-marrow activity and aplastic anemia.

Erythromycin is produced by *Streptomyces erythreus*. It is usually administered orally, but it can be given parenterally. Although erythromycin has relatively few primary uses, it is valuable in treating pharyngitis and pneumonia caused by streptococci in persons sensitive to penicillin. It is also used in treating pneumonias caused either by *Mycoplasma* species or by the organism causing Legionnaire's disease; and it is used in treating pharyngeal carriers of the bacillus responsible for diphtheria.

Therapeutic indications of erythromycin

Clindamycin is a derivative of lincomycin that has better microbial activity and rate of gastrointestinal absorption. As a result, lincomycin has limited use. Clindamycin is active against staphylococci, some streptococci, and anaerobic bacteria. Because it has been associated with pseudomembranous colitis (inflammation of the small intestine and the colon), it must be used with caution. Other antibiotics, however, can cause an identical colitis.

The polymyxins are produced by *Bacillus polymyxa* and are designated as polymyxin A through E. Two of these, polymyxin B and polymyxin E (colistin), are useful in treating infection. Polymyxins B and E are polypeptide antibiotics with an affinity for phospholipids (important elements in cell membranes). Polymyxins accumulate in the cell membrane of bacteria and affect selective permeability. They also react with and affect the membranes of animal cells, resulting in kidney damage and neurotoxicity. Because they are not well absorbed from the gastrointestinal tract, oral administration is occasionally used for the treatment of diarrhea. Polymyxins can be administered by intramuscular injection. They are used primarily in treating infections caused by *Pseudomonas aeruginosa*, but they are also used topically for the treatment of eye and ear infections. The availability of other excellent antibiotics limits their use.

Rifampin, a semisynthetic agent derived from a rifamycin produced by *Streptomyces mediterranei*, inhibits RNA synthesis. It is absorbed from the gastrointestinal tract, penetrates tissue well, including the lung, and is used in the treatment of tuberculosis. Rifampin administration is associated with several side effects, mostly gastrointestinal in nature. The urine, feces, saliva, sweat, and tears can be red-orange in colour.

RNA inhibition

Synthetic chemical agents. Synthetic chemical agents used in treating bacterial diseases can affect bacteria in several ways. Some, such as the sulfonamides, are competitive inhibitors of essential biosynthetic pathways. They prevent the synthesis of folic acid, which is an essential preliminary step in the synthesis of nucleic acids. Sulfonamides are able to inhibit folic acid synthesis because they are similar to an intermediate compound (*p*-aminobenzoic acid) that is converted by an enzyme to folic acid. The similarity in structure between these compounds results in competition between *p*-aminobenzoic acid and the sulfonamide for the enzyme responsible for converting the intermediate to folic acid. This reaction is reversible by removing the chemical and results in the inhibition but not the death of the microorganisms.

Other synthetic chemical agents, such as isoniazid (INH) are similar to other metabolites (vitamins) and interfere with their utilization in the synthesis of essential cellular components. They may also activate an enzyme that destroys a factor essential to the cell. Methenamine, in an acidic environment (urine), decomposes to formaldehyde, which is antibacterial. Nalidixic acid affects the bacterial

cell by reacting with an enzyme that is required for the coiling of DNA. The nitrofurans are unique in that their reduction by the bacterium results in forms of oxygen that are highly reactive and thereby react with and alter essential cellular structures.

Limited use of sulfonamides

The sulfonamides are broad-spectrum agents and were once used widely. Their use has diminished because of the availability of antibiotics that are better and safer and because of increased instances of drug resistance. Sulfonamides are still used, but largely for treating urinary tract infections and preventing infection of burns. They are also used in the treatment of certain forms of malaria. The several forms (congeners) of sulfonamides differ from each other in solubility, half-life, ability to bind to plasma proteins, and potency for inhibiting certain bacteria. All affect bacterial growth by interfering with the synthesis of folic acid. Humans are not usually affected by the drugs because they do not synthesize folic acid but rather obtain it from their diet. Trimethoprim also affects the pathway of folic acid synthesis, but at a point different from that inhibited by the sulfonamides. When they are given together, the sequential blockage of the pathway produced by sulfamethoxazole and trimethoprim markedly enhances the inhibition of folic acid synthesis that would have been achieved by the activity of the sulfonamides alone. As a result, this combination is valuable in treating urinary tract infections, systemic infections, and intestinal tract infections caused by *Salmonella* or *Shigella* organisms. The sulfonamides are relatively safe, but hypersensitivity reactions (rashes, eosinophilia, and drug fever) can occur. Similar reactions are obtained with trimethoprim and with the sulfamethoxazole-trimethoprim combination.

The sulfones are related to the sulfonamides and are inhibitors of folic acid synthesis. They tend to accumulate in skin and inflamed tissue and are retained in the tissue for long periods. Thus, they are useful in treatment of leprosy.

Nalidixic acid, an agent commonly used for the treatment of urinary tract infections, affects an enzyme, termed DNA gyrase, that is required for the supercoiling of bacterial DNA.

The nitrofurans (nitrofurantoin and nitrofurazone) are broad-spectrum agents that undergo chemical reduction, resulting in the production of superoxide and other toxic oxygen compounds. These compounds oxidize essential components of the cell and make them nonfunctional. Nitrofurantoin is given orally, and because it accumulates in urine it is used in the treatment of urinary tract infections. Nitrofurazone is used topically for the treatment of burns.

Isoniazid, ethambutol, pyrazinamide, and ethionamide are synthetic chemicals used in treating tuberculosis. Isoniazid, ethionamide, and pyrazinamide are similar in structure to nicotinamide adenine dinucleotide (NAD), a coenzyme essential for several physiological processes. Ethambutol prevents the synthesis of mycolic acid, a lipid found in the tubercule bacillus. All of these drugs are absorbed from the gastrointestinal tract and penetrate tissues and cells. They are useful in treating tuberculosis. An isoniazid-induced hepatitis can occur, particularly in patients 35 years of age or older.

Forms of fungi

Antifungal drugs. The fungi appear in two morphological forms: a single cell that is round or oval (yeast), and a filamentous form (mold). Fungi differ from bacteria in several ways, including the chemical composition of the cell wall and cell membrane. Unlike bacteria, fungi have a nucleus surrounded by a membrane, an endoplasmic reticulum, and mitochondria. These differences between the bacteria and fungi are reflected in the use of different chemotherapeutic agents. Both antibiotics and chemical agents are used in the chemotherapy of fungal diseases.

Antibiotics. Amphotericin B and nystatin are antibiotics that interact with ergosterol, a type of steroid that is found in fungal membranes; this binding results in the loss of membrane-selective permeability and of cytoplasmic components. These antibiotics do not affect bacteria, because, with the exception of *Mycoplasma* species, bacteria do not have these types of steroids in the cell membrane. Mammalian cell membranes do, however, and there is some toxicity associated with parenteral use of these drugs. Amphotericin B is produced by *Streptomyces nodosus* and is used primarily in the treatment of serious fungal diseases, such as cryptococcal meningitis, histoplasmosis, and blastomycosis. The most serious side effect associated with amphotericin B is nephrotoxicity, although phlebitis and anemia can also result. Nystatin is produced by *Streptomyces noursei* and is used orally or topically for the treatment of mucocutaneous infections caused by *Candida albicans*. Nystatin is virtually nontoxic.

Griseofulvin, an antibiotic produced by *Penicillium griseofulvin*, is given orally for the treatment of several superficial fungal infections of the skin (*e.g.*, ringworm and athlete's foot) and diseases of the hair and nails. Griseofulvin binds to keratin, thus depositing high levels in the skin, which is the site of the infection. Griseofulvin affects the fungus by binding to microtubules, structures responsible for forming mitotic spindles and for processing cell wall components needed for growth.

Synthetic chemical agents. Several nonantibiotic preparations are used in treating fungal infections. Flucytosine (5-FC), a fluorinated pyrimidine, is unique in that it becomes active only when converted to 5-fluorouracil (5-FU) by an enzyme, cytosine deaminase, found in fungi but not present in mammalian cells. Flucytosine inhibits RNA and DNA synthesis. When administered parenterally, 5-FC is used primarily in the treatment of systemic cryptococcal and *Candida* infections and chronomycosis.

A group of antifungal agents, termed imidazoles, bind to fungal membranes and block synthesis of fungal lipids, especially ergosterol, the sterol required for membrane stability. The imidazoles have broad antifungal activity and are active against fungi that infect skin and mucous membranes and those that cause deep tissue infections. Clotrimazole, econazole, and tioconazole are given topically and are used for treating oral, skin, and vaginal infections. Miconazole can be administered topically, intravenously, or by intrathecal injection. It is used in treating skin infections, vaginitis, and systemic infections. Ketoconazole is readily absorbed after oral ingestion. It has broad-spectrum activity and is used in treating skin, mucocutaneous candidiasis, and several systemic fungal infections, such as blastomycosis.

Ciclopirox olamine, a hydroxypyridone, is a topical agent that accumulates in the skin and thus is effective in treating skin infections. It affects dermatophytic fungi (that infest the skin) by inhibiting the uptake of amino acids and other precursors needed for the synthesis of macromolecules. Tolnaftate and undecylenic acid are both used for treating dermatophyte infections.

Antiparasitic drugs. Although most organisms that live in or on humans are parasitic, the term parasite is commonly used in reference to the unicellular protozoans and the multicellular helminths (worms).

Structure of protozoans

Antiprotozoal drugs. The protozoans, unlike bacteria and fungi, do not have a cell wall. They have a nucleus and a cytoplasm that is surrounded by a selectively permeable cell (plasma) membrane. The cytoplasm contains organelles similar to those found in other animal and plant cells (*e.g.*, mitochondria, Golgi apparatus, and endoplasmic reticulum). Thus, most of the antibiotics effective in inhibiting bacteria are not active against protozoans. Amphotericin B, however, reacts with sterols, which are components of both fungal and protozoal membranes. Most of the drugs used in the chemotherapy of diseases caused by the protozoans are derived from plants or are synthetic chemical compounds.

Metronidazole is usually given orally for the treatment of vaginal infections caused by *Trichomonas vaginalis*, and it is effective in treating bacterial infections caused by anaerobes. It affects these organisms by causing nicks in, or breakage of, strands of DNA or by preventing DNA replication.

Iodoquinol inhibits several enzymes of protozoans. It is given orally for treating asymptomatic amebiasis and is given either by itself or in combination with metronidazole for intestinal and hepatic amebiasis. *Balantidium coli* and *Dientamoeba fragilis* infections also are treated with iodoquinol. Emetine, an alkaloid derived from ipecac syrup, is obtained from the roots of *Cephaelis ipecacuanha*, a plant native to Brazil. It is used along with iodoquinol

or chloroquine phosphate as alternative therapy for treatment of severe intestinal and hepatic amebiasis. Emetine is given by injection and can cause serious toxicity. Dehydroemetine is less toxic than emetine and may be used as an alternative drug.

Quinacrine is the drug of choice for giardiasis, an infection of the intestine caused by a flagellated amoeba. Quinacrine inserts itself into DNA, thereby ultimately preventing the synthesis of nucleic acids. It is given orally and can cause yellow staining of skin and sclera and deposition of blue and black pigment in the nail beds.

Trypanosomes are flagellated protozoans that cause a number of diseases. *Trypanosoma cruzi,* the agent of Chagas' disease, is treated with nifurtimox, a nitrofuran derivative. It is given orally and results in the production of activated forms of oxygen, which are lethal to the parasite. Other forms of trypanosomiasis (African trypanosomiasis, or sleeping sickness) are caused by *T. gambiense* or *T. rhodesiense.* When these parasites invade the blood or lymph, the drug of choice is suramin, a nonmetallic dye that affects glucose utilization and hence energy production. Because suramin is not absorbed from the gastrointestinal tract, it is given by intravenous injection. In the late form of trypanosomiasis, when the parasites have invaded the central nervous system, melarsoprol and tryparsamide are administered intravenously. They are used because they can penetrate the central nervous system and affect cellular structures and their functions.

Pneumocystis carinii causes pulmonary disease in immunocompromised patients. These infections are treated with trimethoprim-sulfamethoxazole, which inhibits folic acid synthesis in protozoans. An alternative agent for treatment of these diseases is pentamidine isethionate, which probably affects the parasite by binding to DNA. Because the drug is not well absorbed from the gastrointestinal tract, it is given by the intramuscular route.

Malaria

Malaria is one of the more serious protozoal infections. Chloroquine phosphate, given orally, is the drug of choice for prophylaxis and treatment. In regions where chloroquine-resistant *Plasmodium falciparum* is encountered, however, pyrimethamine, in combination with sulfadoxine, is used for prophylaxis. Both drugs interfere with folic acid synthesis and are well tolerated. Quinine sulfate, along with pyrimethamine and sulfadoxine, are used to treat infections caused by chloroquine-resistant *P. falciparum.* A high level of quinine in the plasma frequently is associated with cinchonism, a mild adverse reaction associated with such symptoms as a noise in the ears (tinnitus), headache, nausea, abdominal pain, and visual disturbance. Primaquine phosphate is given orally to prevent attacks after a person has left an area where *P. vivax* and *P. ovale* are endemic and to prevent relapses with the same organisms.

Anthelmintics. Helminths (worms) can be divided into three groups: cestodes, or tapeworms; nematodes, or roundworms; and trematodes, or flukes. The helminths differ from other infectious organisms in that they have a complex body structure. They are multicellular and have partial or complete organ systems (*e.g.,* muscular, nervous, digestive, and reproductive). Several of the drugs used to treat worm infections affect the nervous system of the parasite and result in muscle paralysis, either spastic or flaccid. Other drugs affect the uptake of glucose and thus energy stores. All are chemical agents and are generally administered orally. There are no antibiotics available for the treatment of these infestations.

Tapeworms attach to the intestinal tract by a sucker or a sucking groove on the head (scolex). Unlike the nematodes and trematodes, tapeworms do not enter the host tissues. The primary drugs used for these infections are niclosamide and praziquantel. Niclosamide inhibits the uptake of glucose by the helminth and therefore the production of energy. It has a spastic or paralytic effect on the worm. Because it is poorly soluble, high concentrations are obtained in the intestinal lumen. Praziquantel also produces tetanus-like contractions of the musculature of the worm. Unlike niclosamide, praziquantel is readily absorbed from the intestinal tract. It is a broad-spectrum anthelmintic affecting both flukes and tapeworms.

Various locations of roundworms

Treatment of roundworms is complicated by the fact that some live in blood, lymphatics, and other tissues (filarial worms) and thus require use of drugs that are absorbed from the intestinal tract and penetrate into tissues. Others are found primarily or solely in the intestinal tract (intestinal nematodes).

Diethylcarbamazine, used for treating filarial worm infections, is absorbed from the intestinal tract. Blood levels are reached quickly, and it has rapid action against the microfilariae. A severe allergic or febrile reaction due to the death of the microfilariae can follow use of the drug. Piperazine causes a flaccid paralysis of the worm and its expulsion from the intestinal tract. It is used as alternative therapy for treating *Ascaris* infection.

Thiabendazole and mebendazole interfere with glucose uptake and consequently with the production of energy. Mebendazole accumulates in the intestine and is used for treating *Ascaris,* hookworm, and whipworm infections. It is well tolerated but abdominal discomfort and diarrhea can occur in patients with a strong infestation. Thiabendazole is rapidly absorbed from the gastrointestinal tract, making it effective against organisms found in tissue. It is used in treating cutaneous larva migrans (creeping eruption), visceral larva migrans, trichinosis, and trichostrongylosis. About one-third of patients treated with thiabendazole have anorexia, nausea, vomiting, and vertigo.

Pyrantel pamoate causes spastic paralysis of helminth muscle. Most of the drug is not absorbed from the intestinal tract, resulting in high levels in the lumen. It is a drug of choice in treating pinworm and *Ascaris* infection and is a recommended alternative therapy for hookworm and trichostrongolosis.

Praziquantel is the most effective drug in treating infections caused by intestinal, liver, and lung flukes. Bithionol is used for treating *Fasciola hepatica* (sheep liver fluke) and *Paragonimus westermani* (lung fluke) infections and is absorbed from the intestinal tract. Tetrachloroethylene is an alternative agent for treating *Fasciolopsis buski* (large intestinal fluke) and *Metagonimus yokogawai* (small intestinal fluke) infection. Praziquantel is the drug of choice for treating schistosomiasis (infections of blood flukes). Metrifonate, a drug used as an alternative agent for *Schistosoma haematobium* infections, is metabolized to dichlorvos, an anticholinesterase agent. Dichlorvos acts on cholinesterase in the helminth and can also cause a reversible inhibition of plasma cholinesterase in patients. Oxamniquine in an alternative oral therapy for the treatment of *Schistosoma mansoni* infestation.

Antiviral drugs. Viruses are among the most common and widespread causes of infectious diseases. They cause such illnesses as influenza, herpes simplex type I (cold sores of the mouth) and type II (genital herpes), shingles, viral hepatitis, encephalitis, infectious mononucleosis, and the common cold. Viruses remain one of the least understood and most difficult of all infectious organisms to control; but this is changing as more is learned about their structure and replication. Viruses consist of nucleic acid, either DNA or RNA, and a protein coat. Because viruses do not have the enzymes that are needed to manufacture cellular components, they are obligate parasites, which means they must enter a cell for replication to occur.

Obligate parasites

The nucleic acid of the virus instructs the host cell to produce viral components, which leads to an infectious virus. In some cases, as in herpes infections, the virus nucleic acid may remain in the host cell without causing replication of the virus and damage to the host (viral latency). In other cases, the production of virus by the host cell may cause the death of the cell. A major problem in treating some viral diseases is that latent viruses can become activated, frequently when the host undergoes stress, thereby producing infectious virus and cellular effects.

Many factors account for the difficulty in developing antiviral chemotherapeutic agents. The structure of each virus differs, and specific therapy is often unsuccessful because of periodic changes in the antigenic proteins of the virus. The need for a host cell to support the multiplication of the virus makes treatment difficult because the chemotherapeutic agent must be able to inhibit the virus without seriously affecting the host's cells.

The greatest success against virus infections has been by increasing immunity through vaccination (influenza, poliomyelitis, measles, mumps, and smallpox) with live attenuated (weakened) or killed viruses. Vaccination has resulted in the total elimination of smallpox. While vaccination has proved to be effective against the specific virus used for smallpox, influenza is caused by viruses that constantly change their antigenic protein, thereby requiring revaccination as the antigenic makeup of the virus changes. Some virus groups contain 50 or more different viruses.

Passive immunization with serum or globulin (antibodies) from immune persons has been used to prevent viral infections. Immune globulins, such as those used against hepatitis, often cause adverse effects, however, and they are effective only for prophylaxis and not for treatment.

Viral replication cycle

An antiviral agent must act at one of five basic steps in the viral replication cycle in order to inhibit the virus. The steps are (1) attachment and penetration of the virus into the host cell; (2) uncoating of virus—*e.g.,* removal of the protein surface and release of the viral DNA or RNA; (3) synthesis of new viral components by the host cell as directed by the virus DNA; (4) assembly of the components into new virus; and (5) release of the virus from the host cell.

Antibiotics. Vidarabine (adenine arabinoside) was isolated from *Streptomyces antibioticus.* It is given intravenously and is effective in treating herpes simplex types I and II, particularly severe herpes encephalitis infections, herpes keratitis (eye infection), and varicella zoster (shingles) infections. Vidarabine is similar in structure to a component of viral DNA (a purine). The host cell adds chemical groups (phosphates) to the antibiotic, and this change causes inhibition of DNA polymerase, an enzyme that catalyzes the formation of DNA. It also incorporates into the DNA molecule of the virus and prevents formation of the DNA strand. Vidarabine does not affect host cells at the concentration used for the inhibition of viral replication. Mutants that code for altered DNA polymerase are not affected by this antibiotic.

Synthetic chemical agents. Amantadine is an oral drug used for the prevention and treatment of the influenza A virus; it is not effective, however, against influenza B virus. The action of amantadine is probably through the inhibition of viral uncoating, thereby preventing the release of viral nucleic acid in the host cell and the synthesis of new virus. Amantadine may also inhibit penetration of the virus into the host cell. A similar agent, rimantadine, has the same mechanism of action but has a lower incidence of adverse effects (nervousness, confusion, drowsiness, and headache) than amantadine.

Treatment of herpes simplex infections

Acyclovir, which can be given orally, topically, or intravenously, is useful in the prevention and treatment of infections with herpes simplex type I and type II, shingles, and herpes keratitis. Acyclovir prevents replication of viral DNA either by inhibiting viral DNA polymerase or by incorporation into the viral DNA. Acyclovir is phosphorylated within infected cells by the action of the enzyme thymidine kinase, which means that the virus is inhibited by the drug more effectively than is the host cell, thus accounting for acyclovir's selective toxicity. Virus mutants that code for an altered thymidine kinase with reduced affinity for the drug are resistant to the drug's effects.

Idoxuridine and trifluorothymidine are used topically to treat herpes simplex keratitis, and both serve as substrates for the herpesvirus-induced DNA polymerase and consequently inhibit production of viral DNA.

Interferons represent a group of nonspecific antiviral proteins produced by host cells in response to viral infections, as well as in response to the injection of double-stranded RNA, some protozoal and bacterial components, and other chemical substances. Interferon results in the production of a protein that prevents the synthesis of viral components from the viral nucleic acid template. The interferons are of interest because they have broad-spectrum antiviral activity and because they inhibit the growth of cancer tissue. The study of interferons has been hampered somewhat because only small amounts are produced by tissue cells. The gene for the production of interferon, however, has been inserted into bacteria by recombinant DNA techniques, thus allowing production of large amounts of antiviral substance, a requirement for further testing and general use. Experimental trials have indicated the potential usefulness of interferon in the treatment of viral infections and some forms of cancer.

CANCER CHEMOTHERAPY

Mechlorethamine, an alkylating agent, is a derivative of nitrogen mustard, a chemical warfare agent. Mechlorethamine was first used in the 1940s in the treatment of cancer and was shown to be effective in treating human lymphomas. Since then, many anticancer (antineoplastic) drugs have been developed and used with much success. At least 10 types of human cancer can be cured in most patients by chemotherapy alone or in combination with surgery and/or radiation.

Toxicity of anticancer agents

Unlike other chemotherapeutic agents, where the goal is to destroy a microbial invader, the treatment of cancer is complicated in that the chemotherapeutic agent is aimed toward human cells, albeit cells that have undergone genetic changes and are dividing at a fast and uncontrolled rate. Because cancer cells are similar to normal human cells, the anticancer agents are generally toxic to normal cells and can cause numerous side effects, some of which are life threatening. These side effects include hair loss, sores in the mouth and on other mucous membranes, cardiac anomalies, bone marrow toxicity, and severe nausea and vomiting. The bone marrow toxicities result in anemia as well as in decreased resistance to infectious agents. Permanent infertility can also result. These adverse effects may require that the drug dosage be reduced or the antineoplastic drug regimen be changed to make the drug tolerable to the patient. Many of the anticancer drugs that are given intravenously cause severe local damage at the injection site if inadvertently injected into the tissue instead of the vein. The person preparing and administering the drugs also must be careful not to come in direct contact with these drugs because some can cause cancer (carcinogenic). While most are administered intravenously, many can be taken orally, and some can be injected intramuscularly or intrathecally (within the spinal cord).

Antineoplastic agents are divided into categories based on their mode of action. Since most of the drugs exert their effects in a certain part of the cell cycle (cell growth phase, cell division phase, resting phase, etc.), many treatment regimens require two or more of these agents. One drug may be used to stop the growth of the cancer cells in a certain phase, whereas another agent may work at a different phase. Using multiple agents, therefore, lessens the incidence of cellular resistance to an antineoplastic agent. The use of multiple agents also often enables the use of lower dosages of each drug, thereby reducing the side effects caused by each. In addition to using complex regimens that employ several drugs, chemotherapy is often combined with surgery to reduce the number of cancer cells and with radiation treatment to further destroy the cells.

Alkylating agents. Alkylating agents were the first anticancer drugs used, and despite their hazards they remain a cornerstone of anticancer therapy. Some examples of alkylating agents are nitrogen mustards (chlorambucil and cyclophosphamide); cisplatin; urea derivatives (carmustine, lomustine, and semustine); alkylsulfonates (bisulfan); ethyleneimines (thiotepa); and triazenes (dacarbazine). These chemical agents are highly reactive and bind to certain chemical groups (phosphate, amino, sulfhydryl, hydroxyl, and imidazole groups) commonly found in nucleic acids and other macromolecules. These agents bring about changes in the DNA and RNA of both cancerous and normal cells. For example, the nucleic acid may lose a basic component (purine), or it may break, or strands of DNA may cross-link. The result is that the nucleic acid will not be replicated. The altered DNA either will be unable to carry out the functions of the cell, resulting in cell death (cytoxicity), or the altered DNA will change the cell characteristics, resulting in an altered cell (mutagenic change). This change may result in the ability or tendency to produce cancerous cells (carcinogenicity). Normal cells

Mechanisms of action

may also be affected and become cancer cells. The alkylating agents can cause severe nausea and vomiting as well as decreases in the number of red and white blood cells. The decrease in the number of white blood cells results in susceptibility to infection. Although alkylating agents may be used in most types of cancer, they are generally of greatest advantage in treating slow-growing cancers. They are not as effective on rapidly growing cells.

Antimetabolites. Antimetabolites are antineoplastic agents that are structurally similar to compounds that are found naturally in the host (vitamins, amino acids, or precursors of DNA and RNA). They incorporate into either DNA or RNA (purine and pyrimidine nucleotides) and interfere with cellular function. Some inhibit an enzyme necessary to macromolecular synthesis, thereby preventing synthesis of essential host materials. Examples of these include antagonists of purines (azathioprine, mercaptopurine, and thioguanine) and antagonists of pyrimidine (fluorouracil and floxuridine). Cytarabine, which also has antiviral properties, interferes with a DNA polymerase, dihydrofolate reductase, which is necessary for the synthesis of tetrahydrofolate and subsequently for the synthesis of the folic acid needed for DNA formation.

Because the antimetabolites primarily act upon cells undergoing synthesis of new DNA for formation of new cells, it follows that most of the toxicities associated with these drugs are seen in cells that are growing and dividing quickly. They are known to cause severe damage to the mucous membranes of the mouth and other parts of the gastrointestinal tract and also to produce skin disorders and hair loss. Anemia can occur, along with a decrease in the number of white blood cells, which are necessary to prevent infections. Methotrexate has been used in low doses for the treatment of rheumatoid arthritis.

Antineoplastic antibiotics. Antineoplastic antibiotics (doxorubicin, daunorubicin, bleomycin, mitomycin, and dactinomycin) are derived from *Streptomyces* species. While they may have antibacterial activity, they are generally too dangerous and toxic for that use. These antibiotics affect DNA synthesis and replication by inserting into DNA or by donating electrons which result in the production of highly reactive oxygen compounds (superoxide) that cause breakage of DNA strands. These agents are associated with blood cell damage, hair loss, and other toxicities common to the antimetabolites and alkylating agents, and severe cardiac or lung toxicity also results. The effects vary in proportion to the dose and length of treatment. These antibiotics are administered exclusively by intravenous infusion.

Hormones. Hormones are used primarily in the treatment of cancers of the breasts and the sex organs. These tissues require hormones, such as androgens, progestins, or estrogens, for growth and development. By countering these hormones with an antagonizing hormone, the growth of that tissue is inhibited, as is the cancer growing in the area. For example, estrogens are required for female breast development and growth. Tamoxifen competes with endogenous estrogens for receptor sites in breast tissue where the estrogens normally exert their actions. The result is a decrease in the growth to breast tissue and of breast cancer tissue. Adrenocorticosteroids are also used for treating some types of cancer. An unusual approach to cancer chemotherapy has been the use of a hybrid molecule (estramustine) that is a complex of an estrogen and a nitrogen mustard. The hormones are the closest approach to a site-specific antineoplastic drug, but they work only on certain types of cancer.

Antagonizing effects

Other agents. A number of other agents are used in the treatment of cancer. Vinblastine and vincristine (vinca alkaloids), derived from the periwinkle plant, along with etoposide, primarily act to stop spindle formation within the dividing cell during DNA replication and cell division. Etoposide, a semisynthetic derivative of a toxin found in roots of the American mandrake, or may-apple plants, affects an enzyme and causes breakage of DNA strands. Hydroxyurea inhibits the enzyme ribonucleotide reductase, an important element in DNA synthesis. It is used to reduce the high granulocyte count found in chronic myelocytic leukemia. Asparaginase breaks down the amino acid asparagine to aspartic acid and ammonia. Some cancer cells, particularly in certain forms of leukemia, require this amino acid for growth and development. Other agents, such as dacarbazine and procarbazine, act through various methods, although they can act as alkylating agents. Mitotane, a derivative of the insecticide DDT, causes necrosis of adrenal glands.

New approaches to cancer therapy. Other agents being evaluated include interferon and monoclonal antibodies. Interferon is an antiviral agent that is effective in some cancers. Monoclonal antibodies are highly specific agents that recognize differences between cells. The approach to their use is twofold: first, to use the antibody to kill cancer cells by direct action; and second, to couple a toxin to the antibody. The antibody is used to recognize a specific cancer cell and to deliver a toxin that kills it.

Interferon and monoclonal antibodies

The BCG vaccine is an attenuated form of the bacillus that causes tuberculosis. It is used to immunize selected persons so as to prevent tuberculosis, and it has been used in the treatment of certain forms of cancer. Other chemicals are used to enhance the immunity to cancer cells.

The decision to use a certain antineoplastic drug depends on many factors, including the type and location of the cancer, its severity, whether surgery or radiation therapy can or should be used, and the side effects associated with the drug. Combinations of anticancer drugs, like combinations of antimicrobials, are often more effective than single agents. Although many regimens have been developed, each must be tailored to the patient. (I.S.S.)

IMMUNOSUPPRESSANTS

The immunosuppressants are a class of drugs capable of inhibiting the body's immune system. Many of the agents included in this category are also cytotoxic (cell poisons) and are used in the treatment of cancer. Cytotoxic agents used as immunosuppressants include antimetabolites (*e.g.*, azathioprine), alkylating agents (*e.g.*, cyclophosphamide), and folic-acid antagonists (*e.g.*, methotrexate; see above *Cancer chemotherapy*). Other immunosuppressants include corticosteroids, prednisone, antilymphocyte serum (ALS), and cyclosporin A. Radiation (*e.g.*, X rays) is also used to suppress the body's immune system.

The action of most cytotoxic drugs or hormonal agents is nonspecific; they may also act upon components of the immune system that are beneficial. Cytotoxic agents are capable of killing immunologically competent cells, but they do not preferentially affect lymphocytes. The cytotoxic agents, with their inherent ability to kill any cell that will replicate, were originally synthesized as antineoplastic drugs. It was soon discovered, however, that these drugs not only inhibit tumour cell growth but are also able to suppress the cell of the immune system. Subsequently, these cytotoxic agents were employed clinically to suppress the immune system in patients undergoing organ (*e.g.*, kidney, liver, or heart) transplants. The therapeutic use of these cytotoxic agents is based on their ability to suppress the recipient's immune system in order to prevent organ or graft rejection. Although most of the cytotoxic agents exhibit immunosuppressant properties, cyclophosphamide and azathioprine are the agents that have been used most frequently in patients who are preparing to undergo organ transplant surgery.

Use in organ transplant surgery

Cyclophosphamide can impair humoral immune reactions as well as cell-mediated immune response. Despite its therapeutic usefulness, cyclophosphamide is an exceedingly toxic drug and has a number of undesirable side effects. Azathioprine exerts its pharmacological action by inhibiting several enzymatic pathways required for the synthesis of DNA. Azathioprine is more effective in suppressing proliferating (dividing) lymphocytes; it is less active against nondividing cells. Like cyclophosphamide, azathioprine is a relatively toxic drug.

Although corticosteroids have been the primary agents employed in immunosuppressant therapy, their precise mechanism of action remains uncertain. It is known that the corticosteroids affect leukocyte function, alter lymphocyte populations, and depress certain serum immunoglobulins. The use of these steroids may lead to undesirable side effects.

Cyclosporin A is a metabolite obtained from a fungus. It depresses certain subpopulations of white blood cells (T lymphocytes and, to some extent, B lymphocytes). Cyclosporin A shows promise in reducing allograft (a transplant between genetically different members of the same species; *i.e.*, persons who are not identical twins) rejection in surgical transplants and may also be of value in the treatment of certain autoimmune diseases. Dublin

Dublin (Irish: Dubh Linn), the preeminent city of the republic of Ireland, is the political, commercial, and cultural capital of the nation. It is a city of contrasts, maintaining an uneasy relationship between reminders of its colonial past and symbols of present-day life.

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

Site. Dublin's geographic site is superb. Situated at the head of a lovely bay, the city straddles the River Liffey where that stream flows eastward through a hill-ringed plain to the shores of the Irish Sea. (The dark bog water made the "black pool"—Dubh Linn in Irish, Dyfflin in Norse—that gave the city its name.) Almost certainly it was this opening from the sea, leading through the mountains to the fruitful central plains of Ireland, that originally tempted wandering Norse raiders to settle there. In spite of its long historical development, Dublin remains a physically small city. From Dublin Castle it is little more than four miles (six kilometres) to the farthest city boundary in any direction. Each year the suburbs jut farther into the countryside, but to the south there is a natural limit posed by the Dublin and Wicklow mountains, which ring the city and provide some of its most beautiful urban vistas.

Climate. With its coastal site on the western seaboard of the Irish Sea, Dublin enjoys a mild climate. The average temperature is lowest in January–February, 42° F (6° C), and highest in July–August, 59° F (15° C). Sunshine averages four hours a day. The mean annual rainfall is 30–40 inches (760–1,000 millimetres), although the rate is higher in the mountains. The period of maximum rainfall occurs in winter, and there are fewer than 10 days of snow a year.

Layout. Dublin is a low-built, steepled city, with few buildings dating from before the 17th century. The Roman Catholic churches are 19th- and 20th-century structures. One of the tallest buildings—Liberty Hall, a trade union headquarters—reaches 17 stories in height, but most of the buildings are no higher than 10 stories.

Norse, Norman, and Georgian, the three elements that constitute the architectural legacy of Dublin, all meet in Dublin Castle. In the first two decades of the 13th century, the Normans obliterated the Viking stronghold and reared a château-fort. When the Georgians built the present red-brick castle, they left two towers of the old structure standing. The castle, the seat of British authority in Ireland until 1922, is now used for ceremonial occasions, especially the inauguration of the republic's presidents, who now reside at Áras an Uachtaráin ("The President's House," formerly the viceroy's lodge) in Phoenix Park.

Dublin Castle

Close to the castle a Viking king of Dublin built Christ Church Cathedral (*c.* 1030), which was replaced about 140 years later by a more magnificent Norman structure. By the 19th century the edifice was in ramshackle condition; it was restored in the 1870s at enormous cost. Its neighbour, St. Patrick's, erected just outside the city walls, was also originally a Viking church that may have been built on an earlier Celtic foundation. The Normans rebuilt it in 1191, and it was enlarged and partially rebuilt over the centuries. It was in a state of collapse when Sir Benjamin Lee Guinness, the brewing magnate and a lord mayor of Dublin, financed its restoration in the mid-19th century. Christ Church is the cathedral for the Protestant diocese of Dublin and Glendalough, whereas St. Patrick's, also Protestant, is the national cathedral. Both have been Church of Ireland (Anglican) churches since the Reformation.

The area between St. Patrick's and the Guinness Brewery on the Liffey is known as the Liberties, having formerly been outside the city walls and under the sole jurisdiction of the archbishop. Since World War II large tracts of this district have been cleared for low-cost housing.

Dublin's early private speculators had a sense of order and beauty as acute as their sense of profit. The city's streets were broad and its garden squares spacious. For their time (the 18th century), the houses were ultramodern—elegant yet simple Georgian and Neoclassical structures designed in the manner of the great English architects Inigo Jones and Sir Christopher Wren. The sweep of red-brick houses, ranged in long terraces, with their well-proportioned windows made a harmonious whole that still stands as a felicitous achievement of urban architecture.

In the southern half of the town, between Trinity College and St. Stephen's Green, Joshua Dawson, one of Dublin's leading citizens, built an impressive residence in 1705. A decade later he sold it to the city of Dublin for the lord mayor's residence, and it still serves this purpose. It was there that the first Irish republican parliament, the Dáil Éireann, met in 1919.

Dawson's neighbours, the equally prominent Molesworths, followed his example and began building houses and entire streets. In 1745–48 the Earl of Kildare erected, at the end of Molesworth Street, a palace, Kildare House, that was renamed Leinster House when he became duke of Leinster. Leinster House is now the seat of the Irish Parliament. Twin Victorian buildings, which were constructed on either side of Leinster House in the 1880s, contain the National Library and National Museum of Ireland. Merrion Square, immediately to the east, and Fitzwilliam Square, to the south, are two of the great 18th-century squares.

The oldest and largest of the city's squares is St. Stephen's Green, which was recorded in 1224 as common grazing land. It was enclosed and bordered with houses in 1663, although the imposing mansions now surrounding it were built principally in the 18th century. By 1887 the parkland was run down, and the Guinness family, whose former residence on the south side of St. Stephen's Green now houses the Department of Foreign Affairs, paid for its rehabilitation.

St. Stephen's Green

From the western side of St. Stephen's Green to the river, and from there up the northern bank to Parnell Square,

The River Liffey, Dublin, with the dome of the Four Courts at right.
Bord Failte Photograph

runs the city's north–south axis. Grafton Street, long Dublin's premier shopping district, was designated for pedestrians only in the 1990s and has become a lively thoroughfare filled with street entertainers. It emerges onto College Green between the University of Dublin (Trinity College) and the 1729 Parliament House, which is now the Bank of Ireland's headquarters. Trinity College is Ireland's oldest university, founded in 1592, though many of its most distinguished buildings date from the 1700s.

Along the quays of the River Liffey are many monumental buildings, including James Gandon's Neoclassical masterpieces of the Custom House (1781–91) to the south and the Four Courts (1786–1802) to the north. The Custom House was burned in 1921 during the war of independence by republicans who wished to destroy British administrative records; the Four Courts was reduced by shellfire and mines at the outbreak of civil war in June 1922. Both have since been rebuilt by the government.

O'Connell Street—first called Drogheda and then Sackville Street—is Dublin's "downtown," an assemblage of shops, cinemas, and snack bars. The only building of any distinction to survive the warfare that swept the street in 1916 and again in 1922 was the General Post Office, headquarters of the 1916 rebellion. Badly damaged in the uprising, it was reconstructed behind its surviving 1815 classical facade in 1929. Opposite the Post Office stood Nelson's Pillar, a landmark for generations of Dubliners. It was built in 1808 by public subscription but was mysteriously blown up late one night in 1966. In 2000 Dublin Corporation began upgrading both the street and its shops.

At the top of O'Connell Street, Bartholomew Mosse constructed his Rotunda Hospital, also known as the Lying-In, which remains a maternity hospital. To support the hospital, he added a pleasure garden, assembly rooms, and a concert hall. Part of the assembly rooms now serves as the historic Gate Theatre. Behind the hospital is Parnell (formerly Rutland) Square, built in 1750. Many of its original Georgian houses are still intact. One, built for the Earl of Charlemont in 1762–65, now houses the Municipal Gallery of Modern Art. The Roman Catholic Pro-Cathedral was built on Marlborough Street, east of O'Connell Street, in 1816. Owing to their antagonism toward Catholicism, the municipal authorities refused to allow the cathedral to be erected on the main thoroughfare.

The 18th-century city commissioners circumscribed the new city with the North and South Circular roads. On Synge Street, close to the South Circular Roads, is the birthplace of the dramatist George Bernard Shaw. North of these peripheral streets the Grand Canal was constructed; to the south of them is the Royal Canal. Both entered the Liffey at the harbour entrance, and both connect with the River Shannon, though only the Grand is now navigable.

Phoenix Park

Dublin's Phoenix Park is the largest enclosed urban park in Europe. With a circumference of 7 miles (11 kilometres), it covers nearly 30 square miles (80 square kilometres) on the north bank of the Liffey. During the first visit by a reigning pontiff to Ireland, in September 1979, the religious service conducted by Pope John Paul II in the park attracted the largest gathering ever recorded in the country. Initially a royal deer park, Phoenix Park was opened to the public in 1747. Its zoo, celebrated for lion breeding, opened in 1831 and effectively doubled its size in 2001 when the African Plains section opened on land donated to the zoo by the president of Ireland. Nearby is Islandbridge, the site of World War I memorial gardens designed by Sir Edwin Luytens.

THE PEOPLE

Demography. During the second half of the 20th century, the population of Dublin and the surrounding area grew annually by only about 1 percent. Initially the trend in migration was from the countryside to the city. During the last quarter of the 20th century, however, central city areas began to lose population while new suburbs southwest and north of Dublin grew. Urban regeneration at the end of the 20th century attracted new dwellers to the inner city.

Religion. The administrative bodies of Ireland's main religious groups are based in Dublin. Although overwhelmingly Roman Catholic, Dublin is the most religiously diverse part of the country. The non-Catholic population has steadily declined since 1922, but Dublin still holds most of the Anglicans in the republic, as well as half of the Presbyterian clergy. Many older suburbs around the southern rim of the city form the "Protestant belt" of Dublin. An increase in the number of persons who profess other religious creeds reflects the growth of evangelical and charismatic Christian groups during the 1970s, and the number of Dubliners professing no religion, especially among the young, has increased.

THE ECONOMY

Industry. Dublin's major traditional industries—brewing, distilling, food processing, and textile manufacturing—all suffered a decline beginning in the 1970s, and this led to inner-city blight. The recession of the 1980s also led to a slump in the building trades. Several industrial estates, however, have been built in the suburbs around the city and, with the help of government grants, have attracted new enterprises, notably computers, electronics, chemicals, and engineering.

Finance and commerce. Dublin is the headquarters for Ireland's chief financial and commercial institutions. The economic pace has quickened markedly since 1973, when the country joined the European Economic Community

Economic resurgence

(EEC; in 1993 renamed the European Community in the European Union [EU]). In addition to the five major clearing banks, which have their main offices in Dublin, there has been a rapid increase in the number of other banks, principally from EU countries. The Irish Stock Exchange, an integral part of the British Stock Exchange system, is also located in central Dublin and is one of the oldest exchanges in the world, trading continuously since 1793.

Traffic through the port of Dublin has dwindled considerably, but an International Financial Services Centre in the former dock area near the Custom House, under the Custom House Development Authority, was set up in 1986. This venture reflected the commitment of Dublin's commercial and financial interests to plans for the single European market, with its attendant abolition of duties and tariffs within the EU.

Transportation. In 1986 Parliament reorganized transport for the capital by establishing Dublin Bus (Bus Átha Cliath) as a subsidiary of Córas Iompair Éireann (CIE), the national transport company. Another subsidiary of CIE, Irish Railways (Iarnród Éireann), provides suburban services and intercity connections with the rest of the country and Northern Ireland. Dublin's international airport is just north of the city at Collinstown.

ADMINISTRATION AND SOCIAL CONDITIONS

National and local government. Dublin is the administrative capital of the republic of Ireland, serving as the headquarters for government departments, their advisory committees, and associated agencies. The two houses of the Irish Parliament, the Dáil and the Seanad (Senate), meet at Leinster House in the centre of the city. The judiciary is based at the Four Courts. More than 40 countries have resident embassies, and several others are represented by honorary consuls. Just under one-third of the Irish electorate lives in the Dublin area's 11 constituencies, which are represented by 48 members of the proportionally elected Dáil.

Locally, three elected authorities administer Dublin: Dublin County Council, Dublin Corporation (for the city), and Dún Laoghaire Corporation (for the port of Dún Laoghaire, a separate borough to the south of the city). Although certain functions are reserved for the elected bodies, city and county managers perform the executive functions. Through the Local Appointments Commission, the state's Department of the Environment names the managers.

Health. Health care services are administered by the Eastern Regional Health Authority (formerly the Eastern Health Board), the largest of the republic's regional health boards. Health care is free, subject to a means test.

Education. The oldest of Dublin's universities is Trinity College (1592), the only college in the University of Dublin. For centuries Trinity was regarded as a bastion of the Protestant Ascendancy in Ireland, and for many years Roman Catholics were barred from taking degrees, though they could still attend. The ban was lifted in 1793 with the passage of the Catholic Relief Act, but Catholics were still not eligible for the college's full benefits until 1873. University College Dublin, a constituent college of the National University of Ireland, is the largest campus in Ireland, with more than 10,000 students. In 1989 the newest university, Dublin City University, was created from the National Institute for Higher Education at Dublin. Also in the capital are a number of other higher educational institutions, including colleges of technology, teacher-training colleges, and specialized vocational colleges.

Trinity College

CULTURAL LIFE

Dublin played a leading role in the cultural renaissance that began in 1884 with the establishment of the Gaelic Athletic Association for the revival of Gaelic games. It was broadened in 1893 with the foundation of the Gaelic League (Conradh na Gaeilge), which maintains its aim of promoting Irish language and folklore. The National Gallery, the Irish Museum of Modern Art, the Project and City Arts Centres, and many privately owned galleries reflect the liveliness of the visual arts. The area known as Temple Bar—bounded by Dame Street, Westmoreland Street, Parliament Street, and the Liffey—has been developed with a mix of boutiques, galleries, and studios.

Theatre and music. Early in the 20th century the cultural renaissance gained strong momentum in Dublin with the opening of the famous Abbey Theatre, an enterprise associated particularly with the poet William Butler Yeats and the playwrights John Millington Synge and Lady Gregory. In addition to producing their works, the Abbey later staged the first performances of Sean O'Casey's major plays. The old theatre burned down in the early 1950s, and with government aid a new theatre was opened in 1966 housing the main Abbey stage and the experimental Peacock Theatre. In 1928 Micheál MacLiammóir and Hilton Edwards started the Gate Theatre Company, which continues to flourish. The state-sponsored Arts Council, headquartered in Dublin, subsidizes the Abbey and Gate theatres and a number of small theatrical groups in Dublin.

The Abbey Theatre

The city's two main commercial theatres are the Gaiety, which stages annual opera seasons, and the Olympia. In 1980 the National Concert Hall was opened, and, after decades of unsuccessful attempts, the capital finally had a major concert venue. Radio Telefís Éireann, the national radio and television station, is also based in Dublin. It employs the country's principal symphony orchestra.

The city has produced a number of internationally famous pop musicians, including Sinead O'Connor and the postpunk band U2.

Publishing. The country's principal newspapers and periodicals are based in the capital. Dublin has two national daily papers, one evening paper, and three Sunday papers. A number of small but influential literary and current affairs magazines are published, both in Irish and in English. Since 1970 there has been an increase in the number of publishing houses devoted to literature, especially poetry.

Sports. Phoenix Park no longer holds races, but racing flourishes at Loughlinstown and Fairy House. There is also a greyhound track at Harold's Cross. The traditional Gaelic games—hurling and Gaelic football—are played at Croke Park, on the north bank of the Royal Canal. International rugby and association football (soccer) matches are held at Lansdowne Road, and Belfield at University College Dublin attracts major competitions. Golf is a popular sport.

History

FOUNDATION AND EARLY GROWTH

From prehistoric times people have dwelt in the area about Dublin Bay, and four of Ireland's five great roads converged near the spot called Baile Átha Cliath, the name stamped by Dublin's postmark. Dublin appeared in Ptolemy's *Geōgraphikē hyphēgēsis* ("Guide to Geography"; *c.* AD 140), and 151 years later "the people of Dublin," it was recorded, defeated an army from the province of Leinster. Yet, despite indications of habitation there 2,000 years ago, the first settlement for which one can discover any historical proof was not Celtic, but Norse.

The Vikings, or Norsemen, invaded in the 9th century (*c.* 831) and built upon the river's south bank on the ridge above, where Dublin Castle rose 400 years later. The Vikings beat off most Irish attacks until 1014, when they were defeated at the Battle of Clontarf on the north shore of the bay. They nevertheless reoccupied the town, and Viking Dublin survived and grew, though eventually the Norse kings were reduced to earls under Irish overlords.

Viking Dublin

In 1167 the Norsemen supported Roderic (Rory O'Connor) of Connaught (Connacht), claimant to the high kingship of Ireland, in driving into exile their overlord Dermot MacMurrough, king of Leinster. Dermot returned in 1170 with an army of Anglo-Normans from Wales and retook Dublin. Alarmed lest his Anglo-Norman vassals should claim Ireland for their own, King Henry II of England hurried over with an army to affirm his sovereignty. This action proved to be the key to Dublin's development, for it was to establish the site as the centre of government.

Until the middle of the 17th century, Dublin remained a small, walled medieval town, dominating only the Pale—the thin strip of English settlement along Ireland's eastern seaboard. In the 500 years to 1660, three uprisings in the city were suppressed, and a Scottish invasion and the ravages of the Black Death were endured.

At the time of the Reformation, Dublin had become Protestant. During the English Civil War the city's royalist defenders, after contemplating joining forces with an armed Irish Catholic confederacy, surrendered the city in 1649 to Oliver Cromwell's English parliamentary army. By the end of the Cromwell era, Dublin was a town of only 9,000 inhabitants. The turreted city wall with its eight gates was a shambles; the two cathedrals tottered; and the dilapidated castle was, as Cromwell himself put it, "the worst in Christendom." Yet, in the 18th century, Dublin was to become the second city of the British Empire.

ASCENDANCY IN THE 18TH CENTURY

The city's remarkable resurgence began at the end of the 17th century, when thousands of refugee Huguenot weavers from France settled in Protestant Dublin after the revocation of the Edict of Nantes, in 1685, curtailed their privileges. Flemish weavers came in their wake, and soon the cloth trades were flourishing. It was not long before Dublin's competition with English cloth interests prompted the British Parliament to impose export restrictions.

In the course of the 18th century, economic prosperity led to the development of Georgian Dublin. Development spread beyond the old medieval walls; more bridges were erected over the Liffey; and splendid new suburbs arose to the north and east. The city that emerged was, in essence, that of the Dublin of today.

Culturally, the century was one of the richest periods in the city's history. Jonathan Swift was dean of St. Patrick's Cathedral between 1713 and 1745, and other noted literary figures—Oliver Goldsmith, Sir Richard Steele, and William Congreve—were active in Dublin. In the New Musick Hall, Handel conducted the first public performance of his *Messiah* in 1742. For members of the Protestant Ascendancy, as the English establishment was called, Dublin was a gay, fashionable city of elegance and wit.

The Georgian period

It was something less than that, however, for Roman Catholics, who constituted the majority of the population. At the beginning of the century the Irish Parliament, dominated by the Protestant Ascendancy, passed the Penal Laws, a series of harsh discriminatory measures against the Catholics of Ireland. These laws disfranchised Catholics, placed restrictions on their ownership of property, hindered them from entering the professions, and obstructed Catholic education. The majority of the population was kept in extreme poverty and degradation.

EVOLUTION OF THE MODERN CITY

In 1801 the Act of Union between England and Ireland abolished the Irish Parliament and drastically reduced Dublin's status. With no governmental duties to compel their presence in Dublin, the leading figures of the Ascendancy returned to England. The city fell into a decline from which it recovered only 150 years later. Dispossessed farmers crowded into the tenantless Georgian houses, reducing these once elegant structures to slums. Anyone who owed more than 10 shillings could be imprisoned, and, until the legislation was revised in 1864, Dublin's jails overflowed with debtors.

With the easing of the Penal Laws, however, a Roman Catholic middle class emerged, sending its sons to university and into the professions. In 1829 the political dexterity of the Irish Catholic lawyer Daniel O'Connell achieved passage of the Emancipation Act, repealing the Penal Laws and enabling Catholics to sit once again in the British Parliament. After reforms in Dublin's municipal government, O'Connell became, in 1841, the first Roman Catholic mayor of the city since the 17th century. For the first time in 200 years Roman Catholic churches and schools were built, and in 1854 the Catholic University of Ireland (now University College Dublin) opened on St. Stephen's Green, with John Henry Newman as rector.

The railways came to Ireland in 1834, when a seven-mile link connected Dublin with the port of Kingstown (now Dún Laoghaire). As a result, suburbs began to grow up along the coast to the south. Suburban development around the city continued and intensified over the next 70 years.

Although Dublin remained modestly prosperous on the surface, it was festering underneath. The city had some of the worst slums in Europe. Infant and child mortality rates were uncommonly high, with tuberculosis constituting a particular scourge; sanitation and hygiene were practically nonexistent. An investigation in 1910 revealed that 20,000 families were each living in only one room. A two-week survey of 22 public houses, or taverns, disclosed more than 46,000 women and 28,000 children among the customers.

As the 20th century opened, political tensions increased. In 1914 the Home Rule Party secured home rule for Ireland from the government of the United Kingdom; but within months, when World War I erupted, the agreement was suspended. For some years before the outbreak of the war, the Irish Republican Brotherhood (Fenians), who had been quiescent since the failure of their rebellion in 1867, had been secretly reorganizing. When war came, they made plans for another rebellion against the British. With the help of the Irish Citizen Army, a small volunteer workingmen's corps, and the Irish Volunteer Army, a rising took place on Easter Monday 1916. Leaders of the movement proclaimed an Irish republic. The rebels occupied public buildings in the centre of the city, which they held for a week. Commerce and industry came to a halt, and a quarter of the city's population of 390,000 went on public relief.

The Troubles of 1916–23

Finally defeated, the rebels were marched through the streets of Dublin to the jeers and abuse of the populace. But the establishment of martial law in Dublin, the execution of the leaders within 10 days, and the mass imprisonment of those thought to be implicated in the uprising roused Irish public opinion as the rebellion itself had not. Guerrilla warfare by the Irish Republican Army spread through the country in 1919, continuing through two years of terror and counterterror. Dublin was one of the worst affected areas in Ireland and for much of those two years was subject to martial law.

A treaty was concluded in 1921 establishing the Irish Free State, but an antitreaty contingent of the republican army protested and took possession of the Four Courts building. The rebels were eventually driven out by artillery, an event that marked the start of 11 months of murderous civil war between the factions that were for and against the treaty. Once again Dublin suffered heavily in the conflict. The end of the civil war in 1923 did not mean the end of gunfire in the streets, however. Political assassinations and armed raids continued until the early 1930s, and hostilities remained a marked feature of Dublin life.

AFTER NATIONAL INDEPENDENCE

Between 1922 and 1932 the first administrations of the new Irish Free State were preoccupied with trying to establish new government institutions and to repair the damage inflicted on the economy by the Troubles of 1916–23. Housing took a low priority, and it was not until the advent of Eamon De Valera's Fianna Fáil government in 1932 that a concerted program of home building got under way. Some of the worst inner-city slums were cleared, and the people moved to new housing projects on the outskirts of the city. With the introduction of better health care, old-age pensions, and children's allowances, the position of Dublin's poor began to improve.

With the outbreak of World War II, housing construction came to a halt because of a shortage of building material, much of which was imported. Since Ireland remained neutral, Dublin escaped the worst effects of the war, although there were isolated bombing incidents. Food, with some exceptions, was plentiful, but the scarcity of gasoline made private transport nonexistent and severely limited public transport. Politically, Dublin had the mysterious atmosphere of other neutral "whispering galleries" like Madrid and Lisbon, heightened by the presence of both Allied and Axis diplomats.

Dublin during World War II

After the war, as shortages eased, the city began again to spread into the surrounding countryside, and more suburbs took shape. In 1969, high-rise apartment blocks were built in the new satellite town of Ballymun; unfortunately, Ballymun proved no more immune than other places in Europe and the United States to social problems like crime and vandalism that attend such buildings. The situation

there aroused criticism that the design of the tower blocks was unsuitable for family living.

This surge in building was a symbol of the prosperity that rejuvenated the city in the 1960s and '70s. Tourism became a major industry, and Ireland's membership in the EU brought more political, economic, and cultural organizations to Dublin. Development slowed with the onset of the economic recession in the early 1980s but quickened again as the economy improved later in the decade. By the mid-1990s what became known as the "Celtic Tiger" was flourishing economically, which led to a further revival in Dublin.

The social and economic changes that have come about since 1945 inevitably put pressure on historic Dublin, and there is an energetic conservation movement. In 1988 the city celebrated its millennium, arousing much thought and comment about Dublin's past and future, especially concerning the quality of its urban life. The city's regeneration was recognized in 1993, when it was designated as the European City of Culture.

BIBLIOGRAPHY

Physical and human geography: JOHN HARVEY, *Dublin, a Study in Environment* (1949, reprinted 1971), offers a general description. V.S. PRITCHETT, *Dublin: A Portrait* (1967), is an introduction, capturing the character of the city. On city planning, see MICHAEL J. BANNON (ed.), *The Emergence of Irish Planning, 1880–1920* (1985). PETER WYSE JACKSON and MICHELINE SHEEHY SKEFFINGTON, *Flora of Inner Dublin* (1984), is an illustrated study. Historic sites and buildings are presented in ADRIAN MACLOUGHLIN, *Guide to Historic Dublin* (1979). The literary landmarks of the city are discussed in VIVIAN IGOE, *Literary Guide to Dublin* (1995); PATRICIA HUTCHINS, *James Joyce's Dublin* (1950); and JACK MCCARTHY, *Joyce's Dublin: A Walking Guide to Ulysses* (1986). Other guide books include CAROL BARDON and JONATHAN BARDON, *If Ever You Go to Dublin Town: A Historic Guide to the City's Street Names* (1988). ALEXANDER J. HUMPHREYS, *New Dubliners: Urbanization and the Irish Family* (1966), is a sociological analysis. A case study of Dublin is included in CHRISTOPHER T. WHELAN and BRENDAN J. WHELAN, *Social Mobility in the Republic of Ireland: A Comparative Perspective* (1984). Current social and economic developments are discussed in the *Administration Yearbook and Diary*, an annual publication of the Institute of Public Administration. Social life and customs are examined in KEVIN CORRIGAN KEARNS, *Dublin's Vanishing Craftsmen: In Search of the Old Masters* (1987); and JOHN O'DONOVAN, *Life by the Liffey: A Kaleidoscope of Dubliners* (1986). RICHARD ELLMANN, *Four Dubliners: Wilde, Yeats, Joyce, and Beckett* (1987), explores literary traditions. JAMES KILLEN and ANDREW MACLARAN (eds.), *Dublin: Contemporary Trends and Issues for the Twenty-first Century* (1999), debate the city's future.

History: JOHN THOMAS GILBERT, *A History of the City of Dublin*, 3 vol. (1854–59, reprinted 1978), is comprehensive. PETER SOMERVILLE-LARGE, *Dublin: The First Thousand Years* (1988), is a modern historical survey. Other histories include GEORGE A. LITTLE, *Dublin Before the Vikings: An Adventure in Discovery* (1957); CHARLES HALIDAY, *The Scandinavian Kingdom of Dublin*, 2nd ed. (1884, reprinted 1969); JOHN PENTLAND MAHAFFY, *An Epoch in Irish History: Trinity College, Dublin, Its Foundation and Early Fortunes, 1591–1660* (1903, reprinted 1970); R.B. MCDOWELL and D.A. WEBB, *Trinity College, Dublin, 1592–1952: An Academic History* (1982); MAURICE CRAIG, *Dublin, 1660–1860* (1952, reissued 1980); CONSTANTIA MAXWELL, *Dublin Under the Georges, 1714–1830*, rev. ed. (1956); and MARY E. DALY, *Dublin, the Deposed Capital: A Social and Economic History, 1860–1914* (1984). JIMMY WREN, *The Villages of Dublin*, enlarged ed. (1987), provides a survey of the history of the newer suburbs. The intellectual, cultural, and political history of the 19th century is surveyed in RICHARD M. KAIN, *Dublin in the Age of William Butler Yeats and James Joyce* (1962, reissued 1972); and TERENCE BROWN, *Ireland: A Social and Cultural History, 1922 to the Present* (1985). PETER SHERIDAN, *44: A Dublin Memoir* (1999), recalls the city over the second half of the 20th century. (B.E./J.O'B.R./Ed.)

Dutch Literature

Of the earliest inhabitants of the Netherlands, only the Frisians have survived, and they have maintained a separate language and literature since the 8th century. The remainder of the Netherlands was colonized by the Saxons and Franks between the 3rd and 9th centuries, resulting in a predominantly Frankish culture in the south and Saxon or an amalgam of Saxon and Frankish language and culture elsewhere.

Under the less nomadic Franks, the south prospered more than the north, and there a literary language first developed. Because of marked differences between the dialects of the east, the centre, and the west (Flanders, with features that linked the coastal dialects with Old English), the development was very gradual. In the early Middle Ages, when Latin and, later, French were the languages of the educated, the vernacular was largely confined to unrecorded oral legend and folk songs. The earliest text that can claim to contain examples of Old Dutch was the early 10th-century "Wachtendonck Psalm Fragments."

This article is divided into the following sections:

MEDIEVAL LITERARY WORKS

Poetry and prose. The work of Heinrich von Veldeke, the earliest known poet to use a Dutch dialect, typified the age's religious zeal, which emanated from the French centres of learning. In addition to his *Eneit* (*c.* 1185), a chivalrous rendering of Virgil's *Aeneid,* and his love lyrics, which were important for German poets, Heinrich produced *Servatius,* a saint's life written in the Limburg dialect. Dutch 13th- and 14th-century texts were generally written in the cultural centres of Flanders and Brabant, where, for reasons of trade, the prevailing influence was French. Throughout Europe the Crusades brought courtly romances into vogue, and Dutch romances, following French models, were written about events from classical history, such as Segher Diergotgaf's *Paerlement van Troyen* ("Parliament of Troy"); about Oriental subjects; or, most popular of all, on themes from Celtic sagas, including the Arthurian cycle. But by the 1260s chivalry was on the decline; the titles of Jacob van Maerlant's later works bear witness to a late 13th-century reaction against romance. Van Maerlant's compendia of knowledge, including his *Der naturen bloeme* ("The Flower of Nature") and *Spieghel historiael* ("The Mirror of History"), answered a demand for the kind of self-instructional literature that long remained a characteristic of Dutch literature. The change in social patterns at this time is also evident in two epic tales. *Karel ende Elegast* ("Charles and Elegast"), probably an original Flemish chanson de geste of the 12th or 13th century, describes with feudal reverence Charlemagne's adventures in the magic world of folklore. *Van den vos Reinaerde* (*c.* 1240; "Reynard the Fox") is the Flemish poet Willem's version of a translation by another Fleming, Aernout, of the French *Le Plaid,* which, by contrast, brilliantly satirizes feudal society and the epic manner.

Mystical writing

Mystical writing reached a remarkable lyrical intensity in the poetry and hortatory prose of a Brabantine laywoman, Hadewijch (late 12th, early 13th century), and this inspired later mystics, greatest of whom was Jan van Ruysbroeck, a disciple of the German mystic Meister Eckehart and the Netherlands' greatest medieval prose writer. His most important work was *Die chierheit der gheestliker brulocht* (1350; *The Adornment of the Spiritual Marriage,* or *The Spiritual Espousals*), concerning the soul in search of God. His work was part of a renewed ecclesiastic concern to instruct the laity, which resulted in a wealth of Bible stories, legends, and didactic short stories. Of these, *Beatrijs,* an early 14th-century Flemish verse rendering of a popular legend, is told with such humanity and restraint that it still inspires modern versions (*e.g.,* those by Maurice Maeterlinck and Pieter Cornelis Boutens).

Songs, drama, and the rhetoricians. The earliest recorded songs suggest a Germanic rather than a Romance tradition. Because the first extant plays—the 14th-century *Abele spelen* ("seemly plays")—were entirely secular (and may have been the first of such in Europe), incorporating romantic themes from the earlier songs, there is reason to attribute the emergence of drama in the Netherlands as much to mime and song as to liturgical action. The only evidence of early liturgical drama is the Latin *Officium stellae* of the 14th century, after which there is nothing until 1448–55, when the play cycle on the seven joys of Mary was first performed at Brussels. Of the many miracle and morality plays, two deserve special mention: *Mariken van Nieumeghen* (late 15th century; "Mary of Nijmegen") and *Elckerlyc* (of about the same date). The first anticipates the Renaissance in its psychology and treatment; the second, entirely medieval in its conception, is the original of the English *Everyman.* Both were written by members of *rederijkerskamers,* or chambers of rhetoric, institutions that spread from the French border in the 15th century. Organized like guilds, with functions similar to those of the French medieval dramatic societies, the chambers were commissioned by the town protecting them to provide the ceremonial and entertainment at religious and secular festivals, and they were influential in popularizing art and morals. Drama by this time was in the hands of the laity rather than the church, and the introduction of secular themes made it necessary to perform outside of religious buildings, using stages or carts. The survival of the chambers depended on literary performance, and members organized national festivals and competitions. A record of one such festival, held in 1561, is the illustrated *Antwerps landjuweel* (1562; "Antwerp National Contest").

The chambers of rhetoric

THE RENAISSANCE AND REFORMATION

The literature of Flanders and Holland must be considered as a whole until about 1585, when the fall of Antwerp marked the final rift between the Protestant north and the Roman Catholic south. The new art of the Renaissance, coming to the Netherlands from Italy through France, first found expression in writers such as Lucas de Heere, who had fled from the Catholic southern provinces for religious reasons. Chapbooks, containing prose versions of medieval romances, folk songs, and *rederijkers* ("rhetoricians") verse; Reformation propaganda; marching songs of the Calvinist revolt against Spain; these and the first sonnets, the first dissertations in the vernacular, and the first grammars of the Dutch language displayed the restlessness of an age of change. So, while the Catholic Anna Bijns was fulminating against Lutheranism in her glowing satirical verse, which was countered later by the Calvinist Marnix van Sint Aldegonde in his polemical attack on the Catholic Church, the echoes of classical antiquity were reaching the Netherlands in the odes, sonnets, and translations of Jan Baptista van der Noot and Jan van Hout. Carel van

Mander, painter and poet, introduced scholarly vernacular prose writing, though the Latin prose of Erasmus had been famous throughout Europe for nearly a century.

Van der Noot's Petrarchan sonnets, written in the manner of the French poet Pierre de Ronsard, were published in London, where he was then in exile for participating in an insurrection in 1567. The two great moderates of the age were the Erasmians Henric Laurenszoon Spieghel and Dirk Volkertszoon Coornhert, liberal Humanists who espoused a social, undogmatic Christian ethic. Spieghel's poetry is generally more intellectual than Coornhert's prose, which was influenced by Montaigne and the Bible, with a remarkably supple and lucid, even entertaining, style. It was Coornhert and his successors, in particular the translators of the Dutch authorized version of the Bible (published in 1637), who laid the foundations of the standard language.

THE 17TH CENTURY

While the Spanish hold on the Catholic south of the Netherlands during and after the Eighty Years' War (1568–1648) caused a decline in Brabant and Flanders, there was a spectacular expansion in Holland, to which artists, intellectuals, and financiers had fled from the Spanish armies. The emergence of Amsterdam and The Hague as capitals of an empire and the birth of civic pride in writers of the "Golden Age" symbolized the final passing of a medieval age belonging to Ghent, Bruges, Liège, and Antwerp.

The writers of the "Golden Age." Spieghel, the greatest of a generation straddling the old and the new, wrote for both the burgher and scholar. His *Nieujaarliedekens* ("New Year Songs") and *Lieden op 't Vader Ons* ("Songs on the Lord's Prayer") continued a medieval tradition in a Renaissance style echoing Erasmian moderation; his learned *Twe-spraack vande Nederduitsche letterkunst* (1584; "Dialogue on Dutch Literature") was intended to popularize the use of a national language. His most scholarly work, the unfinished *Hertspieghel* (1614; "Mirror of the Heart"), was particularly abstruse because it represented a first attempt at philosophizing in the vernacular and in poetry.

The dichotomy inherent in the Renaissance—between popular religious revival and Humanism—was particularly marked in Holland because of the incompatibility of Calvinistic principles with the ideals of pagan antiquity. This caused a tense ambivalence in many writers of the 17th century who took both their religion and their art seriously. Daniël Heinsius, a celebrated Humanist at the University of Leiden, wrote plays in Latin, but he also contributed to the vernacular by writing *Hymnus ofi lof-sanck van Bacchus* (1614; "Hymn in Praise of Bacchus") and an equally devout *Lof-sanck van Jesus Christus* (1615).

A poet, playwright, and painter, Gerbrand Adriaenszoon Bredero took his material from the life of the commoner; his medium was the folk song, farce, or comedy. His secular songs in medieval style and devotional songs in Renaissance verse told of a passionate devotion to women and yearning for religious moderation. While his three tragicomedies were not successful, his three farces marked the zenith of the medieval genre. Contemporary life in Amsterdam provided material for his two comedies, including his masterpiece, *Spaanschen Brabander* (performed 1617).

Amsterdam was the home of the poet and dramatist Joost van den Vondel. Like Bredero, he was self-educated, and he resolved the conflict between artistic and religious leanings only when he entered the Roman Catholic Church at age 54. This was a courageous act of faith at a time when Catholics formed an unpopular minority. It is a measure of van den Vondel's indomitable personality that his attitude toward contemporary people and events, of which he was a fearless chronicler, still prevails even when history has recorded a different view. His plays, however, are too austere for modern readers, although, in his Sophoclean *Jeptha* (1659) and his Baroque masterpieces *Lucifer* (1654) and *Adam in ballingschap* (1664; *Adam in Exile*), he was as great an artist of the Counter-Reformation as his contemporary the Flemish painter Peter Paul Rubens.

Italian Baroque influence

The aristocratic Pieter Corneliszoon Hooft was one of a fortunate few in Holland to bring the refinements of the new art directly from Italy. He lavished an Italianate flourish on his sonnets and plays, the studied prose of his letters, and a monumental unfinished history of the war against Spain. His castle at Muyden became a thriving centre for the entertainment of artists and scholars attracted not only by a mutual interest in poetry, music, and learning but also by the charm of such gifted young women as the Roemer Visscher daughters, Anna and Maria.

Anna Visscher in verse, like her father Roemer in prose, popularized ethics in a manner that was to bring Jacob Cats unmerited fame. Cats's prolix moralizing, pedestrian doggerel, and patronizing tone forced their way into his country's literature if only because of the disastrous influence they had on the taste of their middle-class readership.

A more harmonious individual, Constantijn Huygens, had all the qualities to which Dutchmen of his day might aspire. A man of strict Calvinist principles, he was an able diplomat who wrote trenchant, shrewd, and witty verse and made excellent translations of John Donne's poetry.

Religious poetry. Three clerics contributed religious verse of considerable merit. The Roman Catholic Joannes Stalpaert van der Wiele wrote *Den schat der geestelycke lofsangen* (1634; "The Treasury of Devotional Praise"), containing songs of medieval simplicity and devotion. Jacobus Revius, an orthodox Calvinist, was a master of the Renaissance forms and the sonnet. Ironically, Dirk Rafaëlszoon Camphuysen, removed from his parish because of his unorthodoxy, satisfied a widespread demand for personal, devotional poetry in *Stichtelycke rymen* (1624; "Edifying Poems"). Equally popular was the introspective mystical poetry by the ascetic Jan Luyken, a layman who began by writing hedonistic songs in *De Duytse lier* (1671; "The Dutch Lyre"), containing fine love lyrics.

THE 18TH CENTURY

The appearance in 1669 of the first literary society (*dichtgenootschap*) was an omen of a decline in Dutch literature lasting through the 18th century. Material well-being sapped the vitality of the nation. Even the talented poet Hubert Poot suffered from the delusion of his day that rococo flourish and prescribed form were the criteria of poetry. Prose, too, consisted almost exclusively of translations and bombastic disquisitions. Significantly, Justus van Effen wrote in French before he founded *De Hollandsche spectator* (1731–35). The simple style of his moralizing essays contrasts with the work of his contemporaries, and his descriptive realism links him with two popular Dutch authors, Betje Wolff (byname of Elizabeth Wolff-Bekker) and Aagje Deken (byname of Agatha Deken).

Betje Wolff, essayist and poet, blended rationalism and romanticism in her creative genius. Her association with Aagje Deken as friend and fellow writer produced the classic epistolary novel *De historie van mejuffrouw Sara Burgerhart* (1782; "The History of Miss Sara Burgerhart"), dedicated to "Dutch young ladies." Remarkable for its wit and realism, it owed much to the English novelist Samuel Richardson. Wolff's intelligence and humour also dominated the original didactic purpose of the pair's eight-volume *Willem Leevend* (1784–85).

The first Dutch novel

By the end of the century a number of poets—including Hieronymus van Alphen, Rhijnvis Feith, Jacobus Bellamy, and Antony Staring—were reacting against Neoclassicism. The most admired and influential poet of the period was Willem Bilderdijk, whose versatile genius was almost smothered with excesses of rhetoric but whose Protestant zeal had repercussions in the Réveil (Revival), a Calvinist fundamentalist movement that gave impetus to the literary revival of the 1830s.

THE 19TH CENTURY

Romanticism. Although Jacob Geel's essays in *Onderzoek en phantasie* (1838; "Inquiry and Fantasy") set a new standard in philological and philosophical criticism in Dutch literature, Geel's liberal rationalism was almost swept aside by the growing wave of Romanticism. Simultaneously, the freethinking born of the Enlightenment roused the militancy of the Calvinists, who realized that their entrenched position was being threatened. Willem Bilderdijk and his disciple Isaäc da Costa reminded the nation of its divine mission, and foreign historical novels

(particularly the work of Chateaubriand and Sir Walter Scott) provided models for historical national Romanticism. In 1826 David van Lennep published a paper calling for novels modeled on Scott; and his son Jacob was the first of many writers to respond, with *De pleegzoon* (1833; *The Adopted Son*). Aernout Drost, author of *Hermingard van de Eikenterpen* (1832; "Hermingard of the Oak Burial Mounds"), set at the beginning of the Christian Era, also started a new literary journal, *De muzen* (1834), which, like his novel, was true to the spirit of the Réveil. Two men on the journal's staff, a historian, R.C. Bakhuizen van den Brink, and a future leader of the literary revival, Everhardus Johannes Potgieter, continued the campaign to improve critical standards in *De gids* ("The Guide"), known as the "Blue Butcher" because of its merciless treatment of complacency. Potgieter defined the historical novel, and Anna Bosboom-Toussaint put his ideas into effect, transposing the universal Christian idealism of Drost to the national Protestant faith of the Golden Age. Bosboom-Toussaint's best known book, *Majoor Frans* (1874; "Major Francis"), was not historical, belonging rather to an era of liberal politics and female emancipationists.

Nicolaas Beets, although feted as a national Protestant poet, owes his enduring fame to his sketches in *Camera obscura* (1839), with their stylistic virtuosity and Dickensian observation of detail. Potgieter's allegorical humour was less direct in its appeal, and his quest for originality tended to deprive his style of simplicity and clarity. The perceptive and often scathing critic Conrad Busken Huet, a progressive who left the church, placed Dutch writing in a truer perspective with western European writing. His essays were collected in *Litterarische fantasiën en kritieken* (1868–88; "Literary Fantasies and Criticisms"), and his later work was best represented by *Het land van Rembrand* (1882–84). Meanwhile, a furor had been caused by an entirely unknown writer, Multatuli (pseudonym of Eduard Douwes Dekker), whose *Max Havelaar* (1860; Eng. trans. 1927), a satire of Dutch exploitation of the Dutch East Indies, unexpectedly revealed a stylistic innovator of genius. Dekker's writing, in *Wouterje Pieterse* (1865–77; Eng. trans. 1904) and *Minnebrieven* (1861; "Love Letters"), vibrated between extremes of sentimentality and anarchy, iconoclasm and utopianism. Although poetry as a convention was anathema to him, Dekker was greatly admired by the young men of the new generation, such as Jacques Perk, who wrote sketches in Dekker's humorous style before composing a sonnet cycle, *Mathilde* (published posthumously in 1882), which opened a new epoch in Dutch literature.

De nieuwe gids

Movement of the 1880s. The appearance of the periodical *De nieuwe gids* ("The New Guide") in 1885 marked the beginning of an important renaissance of literature in the northern Netherlands. Unlike the earlier periodical *De gids*, it pursued an exclusively aesthetic ideal. Leaders of the movement were the poets Willem Kloos and Albert Verwey and the violent and lyrical critic Lodewijk van Deyssel. Among others prominent in the movement were the dramatist, poet, and prose writer Frederik Willem van Eeden; Herman Gorter, who became the foremost poet after his poem "Mei" ("May") appeared in 1889; and the poets Pieter Cornelis Boutens and Jan Hendrik Leopold.

THE 20TH CENTURY

The writers of the Dutch revival of the 1880s were essentially individualistic, but in the next generation a new concern for philosophical and social problems became apparent. The poetry of a prominent socialist writer named Henriëtte Roland Holst-van der Schalk was characterized by a desire for justice and charity. The socialist dramas of Herman Heijermans were internationally successful. A group of Naturalist-Realist novelists—including Frans Coenen and, most gifted of all, Marcellus Emants—flourished. Arthur van Schendel made his debut with Neoromantic fiction, and Louis Marie Anne Couperus was at his peak as a stylish chronicler of life in The Hague.

Significant early poets were A. Roland Holst, J.C. Bloem, and P.N. van Eyck, a philosophical poet and essayist. Immediately after World War I two poets emerged: Hendrik Marsman, an advocate of free verse and representative of the Vitalist movement; and the pessimistic Jan Jacob Slauerhoff, whose works reflect the restless romanticism and disillusionment that characterized his life.

The literary periodical *Forum* was founded in 1932 by Menno ter Braak and Edgar du Perron, leaders of a movement that aimed to replace superficial elegance with greater sincerity and warned against the German threat before the war. The most important mid-20th-century Dutch writer, Simon Vestdijk, was originally associated with the *Forum* group, while Ferdinand Bordewijk's terse style produced hauntingly original fiction. The most original poet was Gerrit Achterberg, whose poems explore the boundary between life and death.

During the Nazi occupation, free literature either stopped or was published secretly. The poets known as *Vijftigers* (Men of the Fifties) rejected the reflective lyricism of the interwar years in favour of an experimentalist style that drew on Dada, Surrealism, and primitive and children's art to create a maximum of physicality. Minimal punctuation, neologisms, and startling associative imagery were used in the poetry of Lucebert (pseudonym of Lubertus Jacobus Swaanswijk). The poets of the following decade, among them J. Bernlef (pseudonym of Hendrik Jan Marsman), reacted with a deliberately low-key, "prosy" style. In Hans Cornelis ten Berge's richly allusive poems, the poet's ego is submerged in a closely structured exploration of language, myth, and history. In the 1970s Gerrit Komrij and others returned to traditional forms such as the sonnet and to rhyme, often with knowing and ironic undertones.

Postwar novelists

Postwar novelists showed the influence of the Nazi occupation in various ways. Anna Blaman treated existential solitude, while Willem Frederik Hermans' classically constructed stories and novels, notably *De donkere kamer van Damocles* (1958; *The Dark Room of Damocles*) and *Nooit meer slapen* (1966; "No More Sleep"), compellingly present a hostile universe that is chaotic and unfathomable. War, for Hermans, is simply an intensification of the abject human condition. Gerard (Kornelis van het) Reve, who made his debut as a deadpan chronicler of postwar malaise in *De avonden* (1947; "The Evenings"), concocted, in such books as *Nader tot U* (1966; "Nearer to Thee"), an extravagant and virtuoso blend of fact and fiction in the name of Romantic Decadence. Inventive panache, vitality, and philosophical reflection mark the fiction of Harry Mulisch, from *Het stenen bruidsbed* (1959; *The Stone Bridal Bed*), set in postwar Dresden, E.Ger., to a later treatment of the aftermath of occupation, *De aanslag* (1982; "The Attack"). Though he belongs chronologically to the war generation, Jan Wolkers began writing in the 1960s and brought a visual artist's sensibility to his often brutal stories and novels. Reactions to the painful loss of empire in the East Indies ran the gamut of nostalgia, affection, bitterness, and alienation in the work of Beb Vuyk (byname of Elizabeth Vuyk), Maria Dermoût, and Albert Alberts, and the colonial experience continues to be a source of inspiration. The tradition of sombre and anecdotal realism, dating from the late 19th century, was continued with great popular success by Maarten 't Hart, who in *De aansprekers* (1979; *Bearers of Bad Tidings*) drew fruitfully on the experience of a strict Calvinist upbringing. The "academic" school of writers associated with the magazine *De Revisor*, founded in 1973, preferred elegantly crafted analytical fictions to "mere" storytelling. Fictional miniaturism continued to thrive in short stories by Anton Koolhaas, Simon Carmiggelt, and F.B. Hotz.

It should be emphasized that from the 1930s Dutch literature and Flemish literature have been part of a composite literary culture: the writers, literary organizations, and departments of culture of the two countries have worked in close cooperation. For this reason the interested reader should consult the article BELGIAN LITERATURE: *Flemish.*

The Earth:
Its Properties, Composition, and Structure

If the Earth were reduced to a tabletop globe 50 centimetres (20 inches) in diameter, the portion accessible to direct observation through even the deepest mines and boreholes would be the equivalent of a very thin skin less than 1 millimetre (0.04 inch) thick. It is therefore not surprising that scientific investigators did not develop a picture of the Earth's interior until well into the 20th century, and only since the 1960s have they come to understand the dynamic processes that shape the terrestrial surface.

The Earth is a nearly spherical body with an equatorial radius of slightly more than 6,378 kilometres (3,963 miles). Compared with the other planets of the solar system, it is only of intermediate size and is substantially smaller than the giant planets Jupiter, Saturn, Uranus, and Neptune. The Earth's Moon, which has a radius of 1,738 kilometres, is relatively large in comparison to the Earth itself. This fact has been of great importance in determining the history of the Earth's rotation, for the Earth and the Moon raise tides in the bodies of one another, resulting in the dissipation of energy into heat, which in turn leads to the slowing of the Earth's spin velocity on its axis and the recession of the Moon. In fact, if the present rates of slowing and recession are linearly extrapolated backward in time, the Moon is found to have been impossibly close to the Earth at a time within the geologic record—a seemingly unexplainable paradox. Only very recently has it been shown that the present distribution of continents and oceans produces an anomalously high rate of slowing, and so the Moon need never have been extremely close to the Earth.

The outstanding feature of the Earth as a planet is the presence of liquid water. Water is vital not only for the biosphere but also for the geologic processes of erosion, transport, and deposition that shape the Earth's surface. Yet, if the Earth were closer to the Sun, the water would be vaporized; if farther, it would turn to ice. Two-thirds of the terrestrial surface is covered by oceans. It was long thought that the continents, constituting the remaining one-third of the surface, had been fixed in position throughout the Earth's history. Gradually some Earth scientists dared to suggest that there had been major continental displacements, and finally, during the 1960s, investigators developed the full picture of seafloor spreading and plate tectonics. The continents, though constantly in motion, are in fact the oldest portions of the Earth's surface, for the seafloor is created at ridges and consumed at trenches on a geologically short time scale. Other planets, notably Mars and Venus, have surface features that suggest some elements of plate tectonics, but none is known to be undergoing the constant rejuvenation of the surface as is the Earth.

The fundamental laws of geologic succession, of the differences between igneous rocks (those crystallized from a melt) and sedimentary rocks (those formed by diagenesis of sediments deposited by surface processes), began to be understood toward the end of the 18th century. At about the same time the measurement of the constant in Newton's law of gravitation showed that the specific gravity of the Earth was about 5.5, whereas that of a typical crustal rock was only about 2.7. Obviously, the interior must be much denser, and it became apparent that pressure alone could not explain the difference. Instead, there have to be differences in chemical composition, involving a decrease with depth of the light elements abundant in the crust (oxygen, silicon, and aluminum) and an increase of heavier elements such as iron. With reference again to the other planets of the solar system, it is seen that their densities tend to fall into two groups: the inner planets with densities close to that of the Earth, and the giant planets with appreciably lower densities. The members of the first group probably have iron cores (proposed for the Earth in the early years of the 20th century), while those of the second must contain large amounts of very light elements such as hydrogen.

If the Earth were completely static, it would be virtually impossible to obtain information about the interior apart from the mean density. Dynamism is, however, the mark of the Earth: tectonic plates move, probably driven by slow convection currents within the Earth's mantle; earthquakes occur; and, from the study of earthquake waves, the broad outlines of the interior can be established. The resulting picture of the Earth includes a solid inner core, a fluid outer core whose radius is more than half the planet's radius, a predominantly solid mantle, and a chemically distinct thin crust that contains most of the familiar geologic features. The rigid plates that are driven over the surface consist of the crust and some uppermost mantle, which together make up a mechanically distinct regime called the lithosphere. In addition to producing earthquakes, the motions of the Earth's interior bring to the surface rocks typical of the deep interior as well as heat. Indeed, scientists now realize that it is the heat escaping from the outer part of the Earth that drives the motions that shape the surface. Smaller bodies of the solar system (*e.g.*, Mars and the Moon) have probably cooled to such an extent that convectively driven tectonics no longer operate.

The heat now escaping from the Earth's surface probably comes in the main from radioactivity throughout the mantle. Some heat may still come from that generated when the dense core "fell" into the Earth's centre, and some may be original heat. The question of whether the Earth began hot or cold is not definitely settled, although majority opinion favours a cold origin with intense early heating through radioactivity and the separation of the metallic core. Ages determined by the analysis of radioactive isotopes and their daughter products provide a clue to early history. The Earth as a distinct body is known to have an age of 4.6×10^9 years, and samples of lunar material show a similar age. The oldest continental rocks currently found, however, in Canada, have ages (since the time they solidified) of approximately 3.9×10^9 years. Presumably the record at the Earth's surface of the first 700 million years was erased by the elevated temperatures that prevailed in those times.

That the Earth has a magnetic field has been known at least since the 11th century when the directional properties of suspended magnetic rock (magnetite; also called lodestone) were first used for navigation. Over the centuries the characteristics of this changing field have become better understood, until it now appears that the only plausible cause is some system of motions in the Earth's liquid outer core. These motions, which may be thermally driven like the slow convection currents in the mantle, constitute an electromagnetic dynamo whose electric currents sustain the field. Many problems remain: Why, for example, should the field have reversed polarity at irregular intervals through geologic time? But again, the existence of the field is in all likelihood simply further evidence of the Earth's dynamic structure.

Some other planets, notably Jupiter and Mercury, are known to have magnetic fields. It is interesting that Jupiter and Mercury differ appreciably in density and therefore composition, but both planets must have the internal motions necessary to constitute a dynamo. The Moon probably once had a magnetic field, but its internal dynamo apparently ceased long ago as the fluid interior froze.

The Earth's magnetic field shields the planet from the most direct effects of the ionized gas that constitutes the solar wind, carving out a cavity known as the magnetosphere. The existence of the magnetosphere has in all likelihood played a fundamental role in determining the nature of the Earth's atmosphere and its climate and therefore in the development of life. Yet, the verification of the magnetosphere's existence is a fairly recent accomplishment, dating only from the International Geophysical Year of 1957–58. (G.D.G.)

This article is divided into the following sections:

The figure and dimensions of the Earth

EARLY CONCEPTIONS

The definition of the figure of the Earth—*i.e.,* its size and shape—usually does not involve the description of mountains and valleys but, rather, the size and shape of the mean sea-level surface and its continuation under the land. This hypothetical surface, called a geoid, is a reference surface from which topographic heights and ocean depths are measured. Because of the irregular mass distributions in the Earth and the resultant gravity anomalies, the geoid is not a simple mathematical surface and consequently is not a suitable reference surface for a geometric figure of the Earth (see below).

As reference figures of the Earth, but not for its topography, simple geometric forms are used that approximate the geoid. For many purposes an adequate geometric representation of the Earth is a sphere, for which only the radius of the sphere must be stated. When a more accurate reference figure is required, an ellipsoid of revolution is used as a representation of the Earth's shape and size. It is a surface generated by rotating an ellipse 360° about its minor axis. An ellipsoid that is used in geodetic calculations to represent the Earth is called a reference ellipsoid.

Reference ellipsoid

This ellipsoid of revolution is the shape most often used to represent a simple geometric reference surface.

An ellipsoid of revolution is specified by two parameters: a semimajor axis (equatorial radius for the Earth) and a semiminor axis (polar radius), or the flattening. Flattening (f) is defined as the difference in magnitude between the semimajor axis (a) and the semiminor axis (b) divided by the semimajor axis, or $f=(a-b)/a$. For the Earth the semimajor axis and semiminor axis differ by about 21 kilometres, and the flattening is about one part in 300. The departures of the geoid from the best fitting ellipsoid of revolution are about ±100 metres (330 feet); the difference between the two semi-axes of the equatorial ellipse in the case of a triaxial ellipsoid fitting the Earth is only about 80 metres.

DETERMINATION OF THE EARTH'S FIGURE: A HISTORICAL REVIEW

Spherical era. *The ancients.* Credit for the idea that the Earth is spherical is usually given to Pythagoras (flourished 6th century BC) and his school, who reasoned that, because the Moon and the Sun are spherical, the Earth is too. Notable among other Greek philosophers, Hipparchus (2nd century BC) and Aristotle (4th century BC) came to the same conclusion. Aristotle devoted a part of his book *De caelo* (*On the Heavens*) to the defense of the doctrine. He also estimated that the circumference of the Earth is about 400,000 stadia (a Greek stadium varied in length locally from 154 to 215 metres). Since the length of his stadium is not known with certainty, the accuracy of his estimate cannot be established. This seems to be the first scientific attempt to estimate the size of the Earth. Eratosthenes (3rd century BC), however, is considered to be one of the founders of geodesy because he was the first to describe and apply a scientific measuring technique for determining the size of the Earth. He used a simple principle of estimating the size of a great circle passing through the North and South poles (Figure 1). Knowing the length of an arc (l) and the size of the corresponding central angle (α) that it subtends, one can obtain the radius of the sphere from the simple proportion that length of arc to size of the great circle (or circumference, $2\pi R$, in which R is the Earth's radius) equals central angle to the angle subtended by the whole circumference (360°):

Eratosthenes' measurement

$$l : 2\pi R = \alpha^\circ : 360^\circ. \qquad (1)$$

In order to determine the central angle α, Eratosthenes selected the city of Syene (modern Aswān on the Nile)

because there the Sun in midsummer shone at noon vertically into a well (Figure 1). He assumed that all sunrays reaching the Earth were parallel to one another, and he observed that the sunrays at Alexandria at the same time (midsummer at noontime) were not vertical but lay at an angle $^1/_{50}$ of a complete revolution of the Earth away from the zenith. Probably using data obtained by surveyors (official pacers), he estimated the distance (l) between Alexandria and Syene to be 5,000 stadia. From the above equation Eratosthenes obtained, for the length of a great circle, $50 \times 5{,}000 = 250{,}000$ stadia, which, using a plausible contemporary value for the stadium (185 metres), is 46,250,000 metres. The result is about 15 percent too large in comparison to modern measurements, but his result was extremely good considering the assumptions and the equipment with which the observations were made.

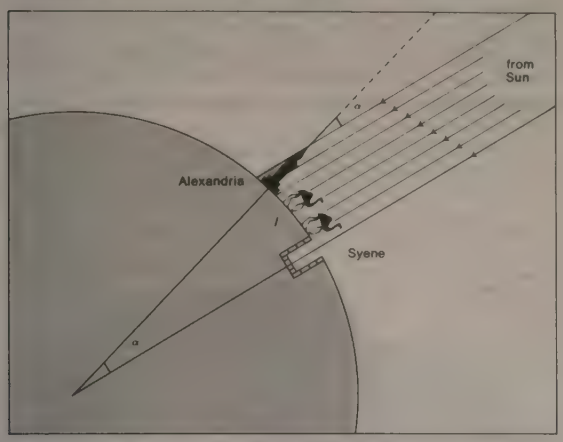

Figure 1: Eratosthenes' arc measuring method (see text).

The introduction of triangulation. A new era in determining the size of the Earth began through the introduction of triangulation. The idea of triangulation was apparently conceived by the Danish astronomer Tycho Brahe before the end of the 16th century, but it was developed as a science by a contemporary Dutch mathematician, Willebrord van Roijen Snell. Snell used a chain of 33 triangles to determine the length of an arc essentially in the way customarily done today. The resulting size of the Earth, however, was 3.4 percent too small. The idea of triangulation is to establish a network of stations that form connecting triangles. One side of the first triangle in the chain, called the baseline, and all angles of the triangles are accurately measured. Using the law of sines from spherical trigonometry, the lengths of all sides thus can be computed starting from a known baseline. When the lengths and angles are known, coordinates can be computed for each point provided that the coordinates of one point and one azimuth are known. Triangulation points are usually placed on the tops of the hills because the neighbouring points must be clearly visible. Commonly, more complicated figures such as quadrilaterals with diagonals are used in triangulation.

Snell's contribution

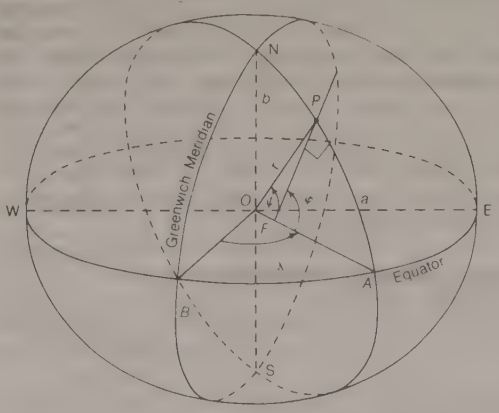
In 1669 Jean Picard, a French astronomer, first used a telescope in determining latitude and in measuring angles in triangulation that consisted of 13 triangles and extended from Paris 1.2° northward. His observations and results were extremely important because his length of arc on a great circle corresponding to 1° was used by the English physicist and mathematician Sir Isaac Newton in his theoretical calculations to prove that the attraction of the Earth is the principal force governing the motion of the Moon in its orbit.

Ellipsoidal era. The period from Eratosthenes to Picard can be called the spherical era of geodesy. A new ellipsoidal era was begun by Newton and the Dutch mathematician and scientist Christiaan Huygens. In Ptolemaic astronomy it had seemed natural to assume that the Earth was an exact sphere with a centre that, in turn, all too easily became regarded as the centre of the entire universe. However, with growing conviction that the Copernican system is true—the Earth moves around the Sun and rotates about its own axis—and with the advance in mechanical knowledge due chiefly to Newton and Huygens, it seemed natural to conceive of the Earth as an oblate spheroid. In one of the many brilliant analyses in his *Principia*, published in 1687, Newton deduced the Earth's shape theoretically and found that the equatorial semi-axis would be $^1/_{230}$ longer than the polar semi-axis (true value about $^1/_{300}$).

First estimate of flattening

Experimental evidence supporting this idea emerged in 1672 as the result of a French expedition to Guiana. The members of the expedition found that a pendulum clock that kept accurate time in Paris lost 2½ minutes a day at Cayenne near the Equator. At that time no one knew how to interpret the observation, but Newton's theory that gravity must be stronger at the poles (because of closer proximity to the Earth's centre) than at the Equator was a logical explanation.

It is possible to determine whether or not the Earth is an oblate spheroid by measuring the length of an arc corresponding to a geodetic latitude difference at two places along the meridian (the ellipse passing through the poles) at different latitudes, which means at different distances from the Equator. This can be seen from Figure 2, in which the geodetic latitude at any point (P) is represented by the angle made between a line perpendicular to the ellipsoidal surface at the point P and the equatorial plane. This angle differs from the geocentric latitude that is determined by a line directed from the point P toward the Earth's centre. Such measurements of arc were made by the astronomer Gian Domenico Cassini and his son Jacques Cassini in France by continuing the arc of Picard north to Dunkirk and south to the boundary of Spain. Surprisingly, the result of that experiment (published in 1720) showed the length of a meridian degree north of Paris to be 111,017 metres, or 265 metres shorter than one south of Paris (111,282 metres). This suggested that the Earth is a prolate spheroid, not flattened at the poles but elongated, with the equatorial axis shorter than the polar axis. This was completely at odds with Newton's conclusions.



$OE = a$ = semi-major axis
$ON = b$ = semi-minor axis
$\angle PFA = \varphi$ = geodetic latitude
$\angle POA = \psi$ = geocentric latitude
$\angle BOA = \lambda$ = geodetic longitude
$OP = r$ = radius vector
N and S = poles
FP normal to ellipsoid at P

Figure 2: Elements of a reference ellipsoid.

In order to settle the controversy caused by Newton's theoretical derivations and the measurements of Cassini, the French Academy of Sciences sent two expeditions, one to Peru led by Pierre Bouguer and Charles-Marie de La Condamine to measure the length of a meridian degree in 1735 and another to Lapland in 1736 under Pierre-Louis Moreau de Maupertuis to make similar measurements. Both parties determined the length of the arcs using the method of triangulation. Only one baseline, 14.3 kilometres long, was measured in Lapland, and two baselines, 12.2 and 10.3 kilometres long, were used in Peru. Astronomic observations for latitude determinations from which the size of the angles was computed were made us-

Efforts to measure the length of a meridian degree

ing the zenith sectors having radii up to four metres. The expedition to Lapland returned in 1737, and Maupertuis reported that the length of one degree of the meridian in Lapland was 57,437.9 toises. (The toise was an old unit of length equal to 1.949 metres.) This result, when compared to the corresponding value of 57,060 toises near Paris, proved that the Earth was flattened at the poles. Later, large errors were found in the measurements, but they were in the "right direction."

After the expedition returned from Peru in 1743, Bouguer and La Condamine could not agree on one common interpretation of the observations, mainly because of the use of two baselines and the lack of suitable computing techniques. The mean values of the two lengths calculated by them gave the length of the degree as 56,753 toises, which confirmed the earlier finding of the flattening of the Earth. As a combined result of both expeditions, these values have been reported in the literature: semimajor axis, $a = 6{,}397{,}300$ metres; flattening, $f = 1/216.8$.

Almost simultaneously with the observations in South America, the French mathematical physicist Alexis-Claude Clairaut deduced the relationship between the variation in gravity between the Equator and the poles and the flattening. Clairaut's ideal Earth contained no lateral variations in density and was covered by an ocean, so that the external shape was an equipotential of its own attraction and rotational acceleration. Under these assumptions, gravity at sea level can be written as a function of latitude φ in the form

$$\gamma_o(\varphi) = \gamma_{\text{Equator}} [1 + B \sin^2 \varphi]. \quad (2)$$

The expression deduced by Clairaut is

$$B = \frac{5}{2} m - f, \quad (3)$$

where $m = \dfrac{\text{centrifugal acceleration at Equator}}{\text{attraction at Equator}}$.

Significance of Clairaut's work

The quantity m is on the same order of magnitude as f; it can be obtained more precisely by calculation than by measurement. Clairaut's result is accurate only to the first order in f, but it shows clearly the relationship between the variation of gravity at sea level and the flattening. Later workers, particularly Friedrich R. Helmert of Germany, extended the expression to include higher order terms, and gravimetric methods of determining f continued to be used, along with arc methods, up to the time when Earth-orbiting satellites were employed to make precise measurements (Table 1).

Table 1: Historical Determinations of the Earth's Radius and Flattening

author	year	method	equatorial radius (in metres)	1/f*
P. Bouguer and P.-L. M. de Maupertuis	1735–43	arc	6,397,300	216.80
G.B. Airy	1830	arc	6,376,542	299.30
A.R. Clarke	1866	arc	6,378,206	295.00
F.R. Helmert	1884	gravimetric		299.25
J.F. Hayford	1906	arc	6,378,283	297.80
W.A. Heiskanen	1928	gravimetric		297.00
H. Jeffreys	1948	arc	6,378,099	297.10

*Flattening denoted by f.

Adoption of the metre unit

Numerous arc measurements were subsequently made, one of which was the historic French measurement used for definition of a unit of length. In 1791 the French National Assembly adopted the new length unit, called the metre and defined as 1:10,000,000 part of the meridian quadrant from the Equator to the pole along the meridian that runs through Paris. For this purpose a new and more accurate arc measurement was carried out between Dunkirk and Barcelona in 1792–98. These measurements combined with those from the Peruvian expedition yielded a value of 6,376,428 metres for the semimajor axis and $1/311.5$ for the flattening, which made the metre 0.02 percent "too short" from the intended definition.

The length of the semimajor axis, a, and flattening, f, continued to be determined by the arc method but with modification for the next 200 years. Gradually instruments and methods improved, and the results became more accurate. Interpretation was made easier through introduction of the statistical method of least squares.

(U.A.U./G.D.G.)

The concept of the geoid. As noted above, the actual sea-level surface of the Earth, even in the absence of the effects of waves, winds, currents, and tides, is not a simple mathematical form. The unperturbed ocean surface must be an equipotential surface of the gravitational field, and because the latter reflects variations due to heterogeneities of density within the Earth, so also do the equipotentials. The particular equipotential surface that coincides over the oceans with unperturbed mean sea level constitutes the geoid. Under the continents the geoid is not directly accessible but is rather the surface to which water would rise if narrow canals were cut through the continents from ocean to ocean. The relationships between land and ocean surfaces, ellipsoid and geoid, are shown in Figure 3. The

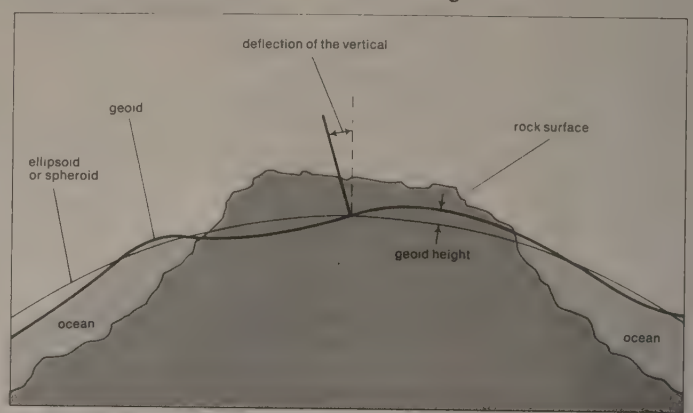


Figure 3: Deflection of the vertical from the geoid to the spheroid.

local direction of gravity is normal to the geoid, and the angle between this direction and the normal to the ellipsoid is known as the deflection of the vertical.

Before the methods of determining the geoid are discussed, it is useful to consider the significance of its undulations or departures from the ellipsoid. The geoid might appear to be a theoretical concept of little practical value, particularly in the case of points on the land surface of the continents, but such is not the case. The elevations of points on the land are determined by geodetic leveling, in which a spirit level is set "level," or tangential to an equipotential surface, and sights are taken on calibrated rods. The differences in elevation determined are therefore with respect to the equipotential and so very nearly with respect to the geoid. The determination in three coordinates of a point on the continental surface by classical techniques thus required the knowledge of four quantities: latitude, longitude, elevation above the geoid, and undulation of the geoid from the ellipsoid at that location. Furthermore, the deflection of the vertical played a most important role, since its components in orthogonal directions contributed errors of the same amounts in astronomical determinations of latitude and longitude. While geodetic triangulation provided relative horizontal positions with high accuracy, the networks of triangulation in each nation or continent began from points whose astronomical positions were assumed. The only possibility of connecting these networks into a global system lay in the computation of the deflections (*i.e.*, the slopes of the geoid) at all initial points. It is true that modern methods of geodetic positioning (discussed below) have altered this approach, but the geoid remains an important concept with definite practical utility.

Determining the form of the geoid with Stokes's formula. The geoid is in essence an equipotential surface of the actual gravitational field. In the vicinity of a local mass excess that adds potential ΔU to the normal Earth's potential at a point, the surface must warp outward in

order to keep the total potential constant. The undulation N is given by

$$N = \frac{\Delta U}{g}, \tag{4}$$

where g is the local value of the acceleration due to gravity. The effect of mass above the geoid complicates the simple picture; it can be allowed for in practice, but it is convenient to consider a point at sea level. The first problem is to determine N, not in terms of ΔU, which is not measured in terrestrial surveys, but rather in terms of departures of g from normal. The difference between the local measured value of gravity and the theoretical value at the same latitude on an ellipsoidal Earth free of lateral density variations is Δg. (The definition of Δg for points on the land surface above sea level is considered below.) The anomaly Δg arises from two causes. The first is the attraction of the mass excess, whose effect on gravity is given by the negative radial derivative of ΔU—*i.e.*, $-\frac{\partial}{\partial r}(\Delta U)$. The second is the effect of the height N, because gravity is measured on the geoid while the theoretical value refers to the ellipsoid. It is shown below that the vertical gradient of g at sea level is given by $\left(\frac{-2g}{a}\right)$ where a is the Earth's radius, so that the height effect is given by

$$\left(\frac{-2g}{a}\right) N = -\frac{2\,\Delta U}{a}. \tag{5}$$

Combining both effects, therefore,

$$\Delta g = -\frac{\partial}{\partial r}(\Delta U) - \frac{2\,\Delta U}{a}. \tag{6}$$

Formally, equation (6) establishes the relation between ΔU and the measurable value Δg, and if ΔU were determined, equation (4) would yield N. However, since both Δg and ΔU contain the effects of mass anomalies throughout an ill-defined region of the Earth, not just beneath the station, equation (4) cannot be solved at a point on the Earth without reference to others. The problem of relating N to Δg in a calculable manner was solved by the British physicist and mathematician Sir George Gabriel Stokes in 1849. Stokes obtained an integral equation for N, in which the integrand contains values of Δg, convolved with a function of their angular distance from the station, and the integral extends over the surface of the Earth. Until the launching of satellites in 1957, Stokes's formula constituted the principal method of determining the form of the geoid, but its application presented great difficulties. The function of angular distance contained in the integrand converges very slowly with that distance, and in the attempt to calculate N at any point—even in countries where g has been extensively measured—uncertainties enter from unsurveyed regions of the Earth that may be at considerable distances from the station. Various methods of extrapolating the gravity anomalies into these regions on the assumption of isostatic equilibrium (see below) were attempted, but the modern approach, which is to combine data from satellites and from ground observers, makes use of the expansion of the potential in spherical harmonic rather than Stokes's integral.

Problems associated with Stokes's formula

The contribution of orbiting satellites. The development of artificial satellites whose orbits could be observed from Earth totally revolutionized man's ability to define the shape of the Earth and its gravity field. A value for the flattening of the ellipsoid that superseded all previous values was obtained within weeks after the launching of the Soviet Sputnik I in 1957. Since that time, scientists have repeatedly refined the geoid with observations from a succession of Earth-orbiting satellites.

Refinement of the geoid

As a satellite moves through the Earth's gravitational field, it experiences forces, in addition to the central attraction, because of irregularities in that field. These forces perturb the orbit of the satellite from the simple form given by Kepler's laws of planetary motion.

It is usual to start with an expression for the potential U of the Earth's gravitational field, in spherical coordinates (r,θ,λ), with origin at the mass centre of the Earth. The gravitational potential U satisfies Laplace's equation, a widely used second-order partial differential equation named after the 18th-century French mathematician and astronomer Pierre-Simon Laplace. Accordingly, it can be expressed as a sum of spherical harmonics (a series of terms by which a variation of a quantity over the surface of a spherical or nearly spherical body such as the Earth can be expressed mathematically to any desired degree of accuracy):

$$U = \frac{MG}{r}\left[1 - \sum_{l=2}^{\infty} J_{l,o}\left(\frac{a}{r}\right)^l P_l(\cos\theta) + \sum_{l=2}^{\infty}\left(\frac{a}{r}\right)^l \sum_{m=1}^{l} J_{l,m} P_l^m(\cos\theta)\cos m(\lambda - \lambda_{lm})\right], \tag{7}$$

where M = the mass of the Earth; G = the gravitational constant; a = the equatorial radius of the Earth; θ = co-latitude; and λ = longitude measured from an arbitrary meridian. The functions $P_l(\cos\theta)$ and $P_l^m(\cos\theta)$ are Legendre polynomials and Legendre associated polynomials (particular solutions of Laplace's equation), respectively. The quantities $J_{l,o}$ and $J_{l,m}$ are dimensionless numbers whose magnitudes give the relative importance of the different spherical harmonic terms (or "wavelengths") in the potential field. They were so designated in honour of Sir Harold Jeffreys, a pioneer in the analysis of the gravitational field in the pre-satellite era. Two features of equation (7) are important. If all of the J's were zero, U would have spherical symmetry and a satellite would move in a constant elliptical orbit, as deduced by Kepler. Properties of this orbit would yield a value for the product MG, but not for M or G separately. Similarly, all observations on actual orbits give the product MG (see below); the mass of the Earth can be determined only when G is measured independently. Second, equation (7) contains no terms in $l = 1$; this is a consequence of the selection of the mass centre of the Earth as origin, with all first moments of mass about that origin vanishing.

The most important term in the summations is that involving $J_{2,o}$. Inserting the value of $P_2(\cos\theta)$, the contribution to the potential is seen to be

$$\frac{3}{2}\,\frac{MG\,a^2}{r^3} J_{2,o}\left(\frac{1}{3} - \cos^2\theta\right).$$

The derivative of this expression with respect to θ is the force per unit mass acting on the satellite in the direction of increasing θ.

Physically, the term represents the effect on the potential of the ellipsoidal shape of the Earth, and it is not surprising, therefore, that $J_{2,o}$, known as the dynamical form factor, is closely related to the flattening f. In fact,

$$f = \frac{3}{2} J_{2,o} + \frac{m}{2}, \tag{8}$$

where m is the quantity introduced in equation (3).

As a satellite in an inclined orbit passes over the equatorial region of the Earth, it experiences a force toward the Equator as a result of the mass in the equatorial bulge. This force represents a torque about the origin, and as in the case of the spinning top or gyroscope, the application of the torque causes the rotation axis of the satellite (normal to the plane of the orbit) to precess about the Earth's rotation axis. The plane of the orbit therefore precesses, resulting in changes in the satellite's path that can be observed from Earth with a high degree of accuracy.

Analysis of the dynamics gives the angular velocity of precession, ω, as

$$\omega = \frac{3}{2} J_{2,o}\left(\frac{a}{r}\right)^2 \sqrt{g_r}\,\frac{a}{r^{1.5}}\cos i, \tag{9}$$

where g_r is the value of g at satellite height and i is the inclination of the orbit. The numerical value of $J_{2,o}$ is approximately 0.001; for a satellite at the height of roughly

740 kilometres, with $i = 20°$, equation (9) gives ω as 6.5° per day. Since the precession persists over the life of the satellite, the rate can be observed with great accuracy.

The higher degree zonal spherical harmonics (the first summation) in equation (7) lead to perturbations of the orbit in the precessing orbital plane. To achieve high accuracy in satellite tracking, special satellites carrying reflectors have been employed in conjunction with ground stations equipped with lasers that may be beamed at such satellites. The time that it takes for a laser pulse to travel to a satellite and back gives its instantaneous distance from the station. This technique represents an advance over an earlier method of geometric satellite geodesy in which a satellite was photographed simultaneously from a number of stations on Earth against a background of stars. That method did not require a precise knowledge of a satellite's orbit and permitted the location of an unknown station on Earth to be fixed relative to known stations. The simultaneous measurement of the distance from ground stations to satellites (*i.e.*, satellite trilateration) allows points on Earth to be precisely located when the orbit is well determined, but the latter, as indicated above, depends on a knowledge of the gravitational field being sought in the experiment. The solution to this apparent paradox is that sufficient observations be obtained to permit the optimum determination of both station coordinates in a global system and orbital parameter simultaneously.

A pioneer satellite designed for geodetic purposes was Lageos (Laser Geodynamic Satellite), launched by the United States on May 4, 1976, into a nearly circular orbit at a height of approximately 6,000 kilometres. It consisted of an aluminum sphere 60 centimetres in diameter that carried 426 reflectors suitable for reflecting laser beams back along their paths. The relatively high elevation was chosen to minimize both the effects of atmospheric drag and local gravity anomalies. Height, however, also attenuates the very effects that are sought, for, as equation (7) indicates, these decrease with increasing values of r. Satellites are therefore most effective at providing values of $J_{l,o}$ to about $l = 16$ (a wavelength on the order of 2,500 kilometres). For larger values of l, measurements of gravity on the Earth's surface, reduced to mean values representative of $1° \times 1°$ areas, must be used.

Satellite orbit analysis

The tesseral harmonics in equation (7), those terms involving $J_{l,m}$, present an additional difficulty. Because the terms represent contributions to the potential having a longitude dependence, their effect in general is averaged out as the Earth rotates under a satellite. The only exception is if the orbit and period of the satellite are such that the satellite tracks over points on the Earth equally separated in longitude, repeating each track precisely after an integral number of cycles. Such a satellite is said to be resonant to a particular value of m. Values of m for which resonant satellites can be found are limited, lying between 9 and 15. For other tesseral harmonics, observations of surface gravity must again be used.

A great advantage of the spherical harmonic expansion is that there is a simple relationship between weighting functions in the geoid undulations, $N_{l,m}$, gravity anomalies, $\Delta g_{l,m}$, and the $J_{l,m}$ terms. It is

$$N_{l,m} = \frac{a}{(l-1)\,\bar{g}}\,(\Delta g_{l,m}) = a\,(J_{l,m} - J'_{l,m}). \qquad (10)$$

Equation (10) is an approximation to the extent that mean values of radius, a, and gravity, $\bar{g}$, have been used. For the construction of maps of the geoid, however, it is usually sufficiently accurate, and it indicates clearly how the undulation coefficients $N_{l,m}$ can be obtained either from the gravity anomalies Δg or from the terms $J_{l,m}$ determined by satellites. The global map of the geoid is obtained by synthesizing the spherical harmonics, weighted by $N_{l,m}$, up to the maximum values of l and m available from the analysis of the observations.

Equation (10) is also useful for predicting the general nature of a map of the geoid, as contrasted to a map of gravity anomalies Δg. Each term in the expansion of N is reduced by the factor $1/(l-1)$ in comparison to the corresponding term in Δg. As l increases, the reduction becomes more significant in that local effects do not appear on the geoidal map.

Figure 4 shows a geoid determined from a combination of satellite observations, including Lageos, and surface measurements of gravity. The departures of the geoid from the ellipsoid range up to about 100 metres, the most pronounced inward warp lying just south of India. There is no obvious direct correlation between continents and oceans, but there are correlations with some of the major features of global tectonics.

Radar altimetry of the ocean surface. As noted above, the geoid over the oceans coincides with mean sea level provided that the dynamic effects of winds, tides, and currents are removed. The surface of the sea acts as a reflector for radar waves, and a satellite equipped with a radar altimeter can be used to sound from the satellite's instantaneous position to the sea. The accuracy with which the sea surface can be reconstructed depends on how precisely the satellite orbit is known, and the reduction of the dynamic effects on the sea surface (waves and semidiurnal and diurnal tides) depends on averaging—

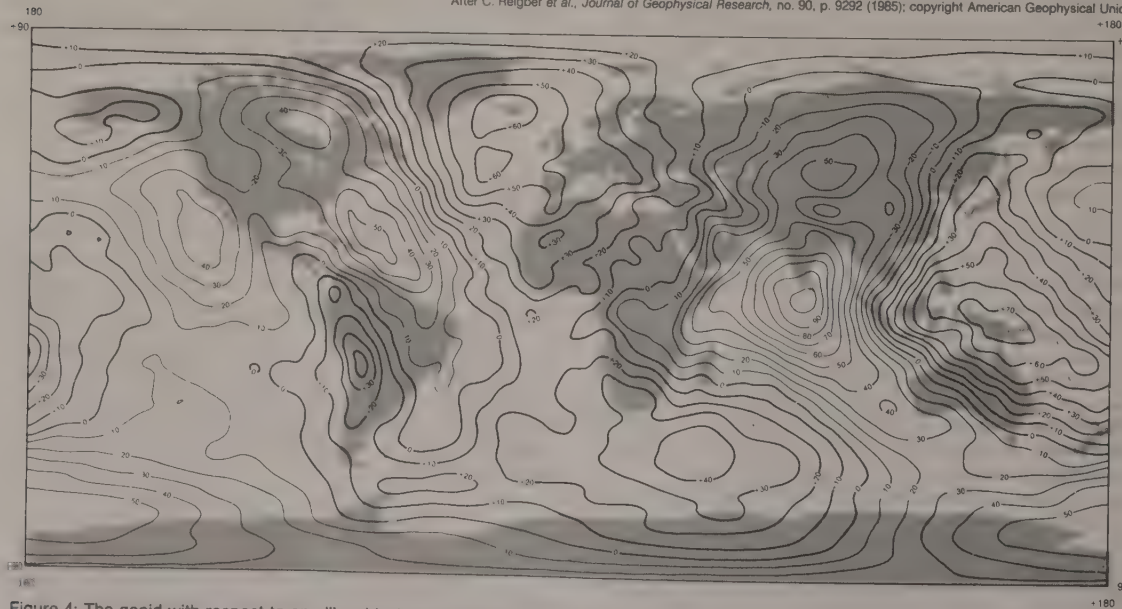

Figure 4: The geoid with respect to an ellipsoid with a flattening, f, of 1/298.257. The contours are at intervals of 10 metres.

over several days—of heights obtained from successive passes over identical points on the Earth.

Mapping of the sea surface with Seasat

The first satellite dedicated to mapping the ocean surface was Seasat 1, launched by the United States on June 26, 1978. Seasat was operational until Oct. 10, 1978, and reproduced its path over the Earth every three days. It sampled elevation every three kilometres along the track and thereby provided average ocean heights for literally millions of points on the sea surface. The precision of a single determination of satellite height above the ocean surface was a few centimetres.

A global map produced from 18-day averages of Seasat elevations is shown in Figure 5. While this is not strictly the geoid because long-term dynamic effects such as those of currents have not been averaged out, it is very close to it. Comparisons between the Seasat map and the geoids determined by the method described above show agreement to about one metre, which is estimated to be the maximum dynamic effect on sea surface "topography." The differences between true geoidal maps and maps of the sea surface are expected eventually to form a powerful tool for physical oceanography. Thus far, the main contribution of Seasat has been to provide a direct visual confirmation of the reality of the oceanic geoid and observations of higher resolution of some parts of the world ocean, as evidenced by a comparison of Figures 4 and 5. The tectonic significance of some of the major features of Figure 5 is discussed below.

EARTH DIMENSIONS—DIAMETER, MASS, DENSITY

Geodetic Reference System 1967

As previously noted, terrestrial arc measurements are capable of yielding a value of the equatorial radius of the Earth, but satellite measurements are greatly superior for determining the flattening. After 10 years of satellite observations the International Union of Geodesy and Geophysics adopted the Geodetic Reference System 1967, defining $a_{equatorial}$, MG, and $J_{2,o}$. Minor revisions to the numerical values were made in 1983. The revised values are as follows:

$$a_{equatorial} = (6{,}378{,}136 \pm 1)\ \text{m},$$
$$MG = (39{,}860{,}044 \pm 1) \times 10^7\ \text{m}^3/\text{s}^2,$$
$$M_A G = (35 \pm 0.3) \times 10^7\ \text{m}^3/\text{s}^2$$
where M_A = mass of the atmosphere,
$$J_{2,o} = (108{,}262.9 \pm 1) \times 10^{-8}.$$

The adopted value of $J_{2,o}$ corresponds to a flattening of $1/298.257$.

While satellite observations determine the value of the product MG to eight significant figures, they cannot determine M and G separately. Because satellites orbit (in general) above the atmosphere, the value of M includes the mass of the atmosphere, but, as shown above, the contribution of the latter to MG is extremely small. The gravitational constant G, measured in the laboratory, is known much less accurately; it is $G = 6.67259 \times 10^{-11}$ $\text{m}^3\text{s}^{-2}\ \text{kg}^{-1}$ (with uncertainty in the last place of decimals). The combination of the laboratory value of G and the adopted value of MG results in a value for the mass of the Earth (including the atmosphere) of $M = 5.98 \times 10^{24}$ kg. With the volume determined by $a_{equatorial}$, the flattening, and the portions above sea level, this value of the mass gives the mean density $\bar{\rho} = 5{,}517\ \text{kg/m}^3$.

There is some indication that $J_{2,o}$ varies slowly with time, as will be discussed below when gravity anomalies are considered in relation to Earth structure. There have been suggestions that G has varied with time throughout the history of the universe and that it is scale-dependent. In the latter case, values determined in the laboratory would not be appropriate for terrestrial or astronomical problems. Evidence for either a time- or scale-dependence of G remains inconclusive.

For many years there has been speculation about the extent to which the actual flattening of the ellipsoid coincides with the theoretical form of a mass of fluid, of the same mass and rotation rate as the Earth, in hydrostatic equilibrium under its own attraction and rotational acceleration. In the pre-satellite era, neither the actual flattening nor the theoretical form were known with sufficient accuracy to permit a meaningful comparison. Recent estimates of the flattening, in the case of hydrostatic equilibrium, for a body free of lateral density variations are close to $1/299.5$; the actual flattening, $1/298.257$, is therefore slightly greater. Although some investigators have suggested that the discrepancy represents an inheritance from the time when the Earth was rotating more rapidly on its axis, the most probable explanation is that it is simply one effect of the recognized lateral heterogeneity in density of the real Earth.

The gravitational field of the Earth

THE NATURE OF GRAVITY

Acceleration due to gravity

It is a familiar phenomenon that an object released above the Earth's surface accelerates toward the Earth. This phenomenon is a special case of universal gravitation—all mass within the universe attracts all other mass. The acceleration in this special case is known as the acceleration due to gravity, denoted g. Reference has already been made above to the fact that g varies over the Earth's surface and that this variation is intimately related to the shape of the sea-level surface, or geoid. In this section the nature of gravity, its measurement, and the relationship of gravity variations to the internal structure of the Earth are discussed.

After J.G. March and T.V. Martin, *Journal of Geophysical Research*, no. 87, p. 3276 (1982), copyright American Geophysical Union

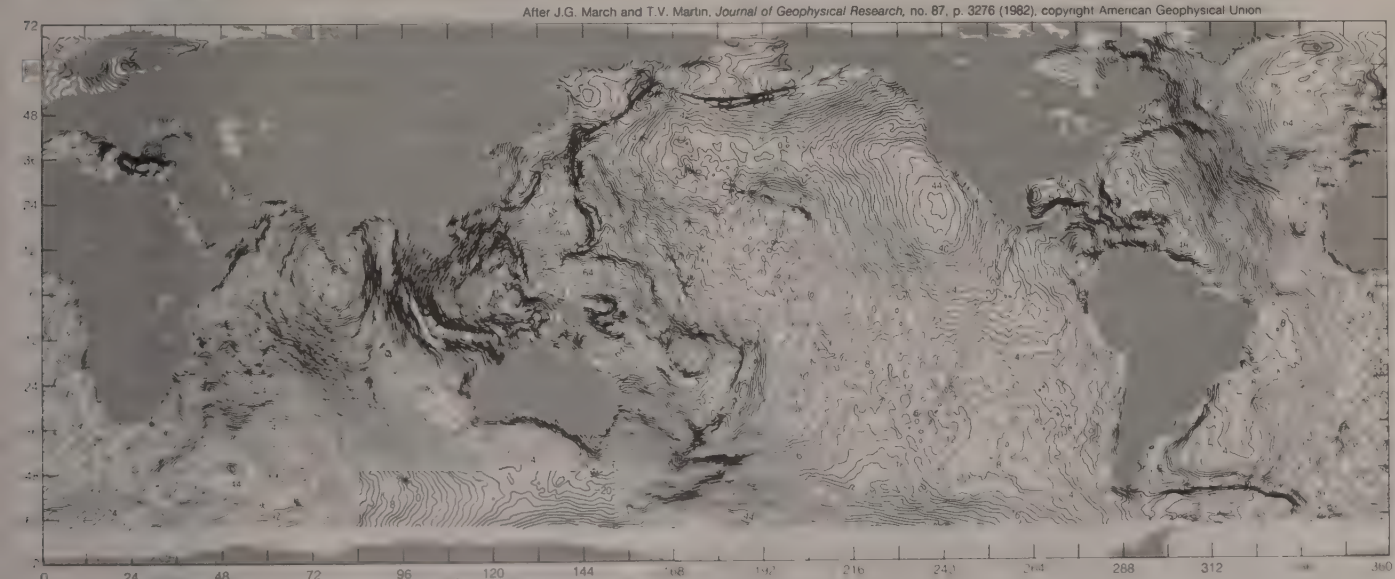

Figure 5: Sea-surface topography based on altimeter data from the Seasat 1 Earth-orbiting satellite. The elevation contours of the mean sea surface are at two-metre intervals.

Newton put forth the law of gravitation for particles of mass m_1 and m_2 separated by a distance r in the form

$$F_{12} = \frac{Gm_1m_2}{r^2}, \tag{11}$$

where F_{12} is the force of attraction of either particle on the other and G is a constant whose numerical value depends on the system of units employed. The application of Newton's law to bodies rather than to particles involves, in general, integration of the effects between differential elements; however, Newton also established the very convenient result that a uniform sphere attracts as though its mass were concentrated at the centre. This led to the possibility of measuring G in the laboratory, first exploited by the English physicist and chemist Henry Cavendish, by observing the force between massive spheres.

In the International System of Units (SI), the modern (as revised in 1986) value for the gravitational constant is $G = 6.67259 \times 10^{-11}$ m^3s^{-2} kg^{-1}. While the numerical value depends on the system of units, the apparently small magnitude of G is real. Gravitational forces between bodies of less than terrestrial size are indeed small, as compared, for example, to electrostatic forces or the magnetic forces between electric currents.

The acceleration due to gravity, g, is the force on a unit mass. In equation (11), if $m_1 = 1$ and $m_2 = M$, the mass of the Earth, the value of g on a spherical, uniform, non-rotating Earth is found to be

$$g = \frac{GM}{a^2}, \tag{12}$$

where a is the Earth's radius.

On the real Earth, departures from the spherical shape and uniformity and the effect of rotation all cause g to vary over the planet's surface. For example, the average value of g is close to 980 centimetres per second per second, but values at sea level range from about 978 near the Equator to 983 at the poles. Superimposed on this variation are the effects of internal structure, usually a small part of one centimetre per second per second. To describe these variations, a smaller unit has been introduced. In geophysics, one centimetre per second per second is known as the gal (after Galileo); 1×10^{-3} gals equal one milligal (mgal), which is the usual unit in which internal effects are measured. Since g itself is very nearly 1,000 gals, the milligal is approximately one part in 1,000,000 of g itself. Modern methods of measuring gravity approach a precision of one microgal, or 1×10^{-3} mgal.

Gravity at any point on the Earth is not constant in time but varies periodically with the tide-producing attractions of the Sun and Moon. The tidal variation has been measured for some years, and its analysis provides information on the yielding of the Earth under tidal forces.

While the emphasis in this section is on the uses of gravity measurements to study the Earth itself, it should be noted that a knowledge of the value of g is required, particularly in standards laboratories, for the measurement or calibration of other physical quantities. Such is the case whenever the weight of a known mass m is used as a standard of force, as, for example, in the absolute pressure exerted by a column of mercury in a barometer. The geophysicist is usually called upon to provide the best value of g for these locations.

BASIC CHARACTERISTICS OF THE TERRESTRIAL FIELD

Variation with latitude. Even if the Earth were of uniform density or uniformly stratified in layers of constant density, gravity at sea level would increase from the Equator to the poles because of the combined effects of the planet's rotation and spheroidal shape. The effect of rotation arises from the fact that any body on the Earth experiences a centripetal acceleration given by $r\omega^2$, where r is the perpendicular distance to the axis of rotation and ω is the angular velocity of rotation of the Earth on its axis. Part of the inward gravitational attraction of the Earth must provide centripetal acceleration simply to hold the body on the planet's surface and thus does not appear in the weight of the body or in measured g. Gravity therefore decreases as r increases from the poles to the Equator. Rotation, however, also distorts the sea-level shape into the ellipsoidal form, so that points near the poles are closer to the Earth's centre of attraction. The effects of rotation and shape are thus cumulative.

The effect of the Earth's rotation

As mentioned earlier, the variation of gravity on this ideal ellipsoidal Earth was investigated by Clairaut, who showed that the expected relationship was

$$\gamma_o(\varphi) = \gamma_{\text{Equator}}\,[1 + B \sin^2 \varphi], \tag{13}$$

where $\gamma_o(\varphi)$ is the sea-level value of gravity at latitude φ and B is a constant incorporating the effects of shape and rotation. If the potential of this field is expanded as a series of spherical harmonics (see above), it is found to contain a single latitude-dependent term involving P_2 (cos θ) where θ is colatitude. The numerical coefficient of this term is known as $J_{2,o}$. The three quantities B, $J_{2,o}$, and the flattening f of the ellipsoid are obviously interrelated, the relationships having been given above in equations (3) and (8).

Clairaut's equation as given is accurate only to the order of f; analysis to higher order of small quantities shows that additional terms in (sin φ) are involved. The quantity γ_o is a fundamental reference against which measured values of g may be compared to study all effects other than those of latitude. In the pre-satellite era the constants in the expression were obtained by fitting the measured values of g, distributed over the Earth, to the theoretical form; adoption of the constants by the International Union of Geodesy and Geophysics led to the International Gravity Formula. With the international adoption of MG, a, and $J_{2,o}$, it is more precise to compute γ_o. The adopted values of the latter lead to

$$\gamma_o = 978.03185\,[1 + 0.005278895 \sin^2\varphi + 0.000023462 \sin^4 \varphi]\ \text{gals}. \tag{14}$$

Variation with elevation. Gravity on the continents of the Earth is rarely measured at sea level, so that, if the measured value of g is to be compared with γ_o, a correction for height must be applied.

From the expression for gravity on a spherical Earth, the effect of increasing the distance from the Earth's centre is immediately obtained, as

$$\frac{\partial g}{\partial r} = -\frac{2GM}{r^3} = \frac{-2g}{r}. \tag{15}$$

At sea level the gradient is equivalent to −0.3086 milligal per metre; the departure of the Earth from spherical shape can usually be neglected when the gradient is required. This is the rate of decrease of g that would be observed if one went up through the open air above sea level without additional mass being interposed. A measured value of g at height h may then be compared with the value of γ_o at the same latitude by forming the expression

$$\Delta g_{\text{F.A.}} = (g + 0.3086h \times 10^{-3}) - \gamma_o, \tag{16}$$

where h is in metres and $\Delta g_{\text{F.A.}}$ is in gals. The result is known as the free-air anomaly, with anomaly signifying the difference between a measured and a theoretical quantity and free-air indicating that g has been reduced to sea level by application of only the free-air term. In comparing points on the land surface with those at sea level, however, there is the additional effect at the higher point of the attraction of mass above sea level. Pierre Bouguer, whose work on arc measurements was noted earlier, realized this and applied a negative correction to g by approximating the actual topography to an infinite horizontal slab of thickness h and uniform density ρ. The attraction of such a slab, in centimetre-gram-second units, is easily shown to be $2\pi G\rho h$. The provision of this effect results in the so-called Bouguer anomaly

Free-air anomaly

Bouguer anomaly

$$\Delta g_B = [g + (0.3086 \times 10^{-3} - 200\pi G\rho)\, h] - \gamma_o \tag{17}$$

where h, as before, is in metres and Δg_B is in gals.

With a typical crustal density of 2.67 grams per cubic centimetre, the inclusion of the Bouguer term predicts that gravity decreases with increasing height of the land surface

at approximately 0.20 milligal per metre, as contrasted with the free-air decrease of 0.3086 milligal per metre. For gravity stations at sea, a slightly different Bouguer term is employed, which effectively replaces the water under the station with rock of normal crustal density.

At first sight, Bouguer's approximation for mass above sea level appears very crude, particularly in regions of irregular topography. In practice, however, it has turned out to be extremely efficacious. In most cases, an additional correction for the terrain in the immediate vicinity of the station only has to be applied within mountain belts.

Free-air anomalies and Bouguer anomalies both find a place in geodesy and geophysics, but it is important to recognize their difference. Because no allowance is made for the effect of mass above sea level in computing the free-air anomaly, the full effect of this mass remains. Indeed, the free-air anomaly is very nearly what would be observed if all of the continents were condensed to sheets of mass "buttered" over the geoid, allowing gravity to be measured everywhere on that surface. The free-air anomaly is therefore used in geoidal computations; it is, for example, the quantity Δg that was introduced earlier (equations 6 and 10). Nevertheless, as the attraction of the topography is not provided for, the free-air anomaly is strongly correlated locally with height to the extent that effects internal to the Earth are obscured. For this reason, Bouguer anomalies are normally used for the study of internal density variations. Yet again, on a broader scale, the Bouguer anomaly itself shows strong correlations with height, rising to positive values of several hundred milligals over the oceans and plunging to negative values of the same magnitude over mountain ranges. In extreme cases, the free-air anomalies remain closer to zero than do the Bouguer anomalies, suggesting that the Bouguer term has greatly overcorrected for the attraction of the topography. Such can only be the case if topographically high regions are somehow compensated for by mass deficiencies, or "roots," beneath and the oceans by rocks of greater than normal density beneath the seafloor (sometimes called "anti-roots"). This is the concept of isostatic compensation (see below).

Variation with internal density distribution. If the Earth were horizontally stratified so that density varied only with depth, the Bouguer anomaly would be everywhere close to zero. In fact, because the Earth is heterogeneous, the gravitational anomaly field displays "roughness" over a very wide range of length scales and amplitudes. When the distribution of excess or deficiency in density is known, the effect on gravity at any point can be determined by the straightforward application of Newton's law (equation 15) to all elements, making it possible to obtain the vertical component and integration over the limits of the distribution.

Geophysicists seek, however, to infer density distributions and derive from them insights into geologic structures. This process is known as interpretation; it is nonunique because different structures can produce the same anomaly at the surface of the Earth. This fact is clearly apparent in the very local anomaly shown in Figure 6. Since a sphere attracts as though its mass were concentrated at the centre, all spheres centred at the same point and representing the same excess mass produce identical anomaly curves. The diagram indicates two possibilities: The larger sphere could be a mass of more basic rock, or the smaller sphere a mass of metallic ore. Without further information, however, the densities and radius cannot be separated. The shape of the profile does, nevertheless, indicate the depth to the centre.

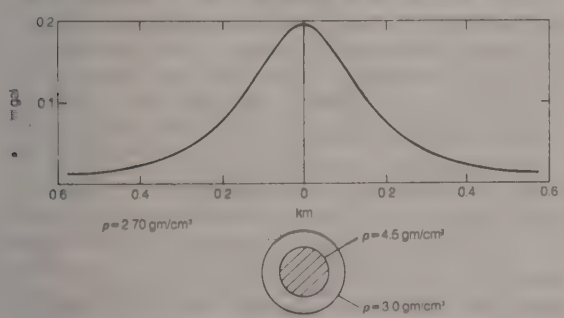

Figure 6: Two spherical dense bodies that produce identical Bouguer anomalies.

In general, gravitational effects increase with the scale of a structure. If the length scales in Figure 6 were increased by a factor of 100, yielding a structure of crustal dimensions, the peak anomaly would be 20 milligals rather than 0.2 milligal (though on this scale a body within the crust having a density of 4.5 grams per cubic centimetre would be most unlikely on geologic grounds).

The Earth contains a number of interfaces at which the normal variation of density with depth suffers discontinuities. These include the Mohorovičić discontinuity (or Moho) at the base of the crust, the core–mantle interface, and surfaces of mineralogical phase change within the mantle. The warping of any of these boundaries from its normal position can produce gravity anomalies at the Earth's surface. Since the amplitude of warp is normally very small compared with the depth of the interface, the effect can be represented by a surface distribution of anomalous mass smeared over the interface. If the densities above and below the interface are ρ_1 and ρ_2, an upward warp of amplitude y is equivalent to a surface density

Warping of the Earth's boundaries as a source of gravity anomalies

$$\sigma = (\rho_2 - \rho_1)\, y. \tag{18}$$

When the free-air gravity anomaly field Δg is available as the sum of spherical harmonic terms, these terms may be inverted directly to give the equivalent term in the spherical harmonic expansion for σ, provided the depth z of the interface is specified. The theory of spherical harmonics gives

$$\sigma_l = \frac{1}{4\pi G}\left(\frac{2l+1}{l+1}\right)\left(\frac{a}{a-z}\right)^{l+2}\Delta g_l, \tag{19}$$

where a is the Earth's radius and l is the degree of the spherical harmonic. The solution obviously becomes unstable at larger values of l in terms of the assigned z. In the expansion of the Earth's field, however, the first few terms beginning with $l = 2$ (but omitting the flattening term $J_{2,0}$) could be due to long wavelength warpings of boundaries as deep as the core–mantle interface. On the other hand, any warping of a surface of discontinuity in density represents a departure from hydrostatic equilibrium, which must be dynamically maintained by motions of the Earth material. Density variations through the material will produce gravitational effects that are intermingled with those of the boundary itself. There is, as yet, no final explanation for the lowest harmonics in the gravity field. The most promising option appears to be a search for correlations with broad anomalies in seismic wave velocity by means of seismic tomography (see below *Seismology: Wave-velocity and density distributions*).

MEASUREMENT OF GRAVITATIONAL ACCELERATION

For the study of the shape of the geoid or of large-scale structures in the Earth, values of g are required with a precision of one milligal or better. This implies a measurement accurate to one part in 10^6 of g itself. For more local studies, as in the use of gravity measurements for geophysical petroleum and mineral prospecting and for the study of the tidal variation of g at a fixed site, much higher precision approaching the microgal level is required. In order to provide for all requirements, it is convenient to separate measuring systems into two classes: (1) absolute systems, in which the actual value of g in correct acceleration units is obtained at a site without reference to any other point; and (2) relative systems, in which differences in g between stations or the time variation of g at one station are measured. To the accuracy sought, the first of these is much the more difficult.

Absolute measurements. The most fundamental and straightforward method of measuring g is to measure directly the acceleration of a body falling in a vacuum toward Earth, but until the mid-1900s timing systems of sufficient accuracy were simply not available. All older absolute measurements were based on measuring the period

Pendulum measurements

of swing of some form of physical pendulum. The period of a simple or mathematical pendulum is known to be

$$T = 2\pi\sqrt{l/g}, \qquad (20)$$

where l is the length from the support to the hypothetical "bob" in which all mass is concentrated. The simple pendulum does not exist, but in any real form that can be swung from supports, two points, on either side of the mass centre, can always be found for which the periods are equal. The distance between these points is equal to l, the length of the equivalent simple pendulum, so that when equality of periods is found by experiment and adjustment, equation (20) can be solved for g. The reversible physical pendulum, as it is known, was employed by the British physicist Henry Kater in 1818 and by later workers up to 1940. Until 1968 all quoted values of g over the Earth were based on pendulum measurements made in Potsdam, Germany, in 1906, other points being determined by relative measurements from that site. By the middle of the century it became apparent that the Potsdam standard was in error by at least 15 milligals, but the methods then available were still not able to provide an absolute value with which to correct to one milligal. In 1952 Charles Volet of France described observations based on a free-fall apparatus in which a graduated rule was dropped in a vacuum in a tall chamber and photographed at precise time intervals as it passed the optic axis of a camera. Alignment of the graduations with a reference line on the photographs permitted g to be determined through the elementary equation

$$s = \frac{1}{2} gt^2, \qquad (21)$$

where s is the distance fallen from rest in time t.

Variations and modifications of the falling-rule type of apparatus were employed in other countries. In 1967 A.H. Cook published the results of measurements made in London in which the object dropped was not a rule but a small sphere, which was recorded as it passed two optical systems. The small-body technique led the way to portable absolute systems, as opposed to fixed installations in standard laboratories. The first portable system was developed by James A. Hammond and James E. Faller in the United States in 1967 largely as a result of the availability of lasers that could produce highly directional beams of coherent light. In this system, the object dropped is a corner cube reflector, which reflects a light beam back along precisely the path through which it enters the evacuated chamber. Laser light directed into the chamber is split by a partial reflector, part of the beam traveling upward to be reflected by the falling cube and part of it being reflected in an identical fixed cube. The mixed light beam leaving the chamber displays alternating maxima and minima of intensity as the cube falls, depending on whether the mixing beams are in phase or antiphase. A photomultiplier tube measures the light. When the output of the photomultiplier is recorded on a precise time base, the falling cube can literally be tracked wavelength by wavelength of the laser light, and g can be determined by equation (21). A single drop can be made in less than one minute and an absolute value of g with an accuracy approaching 20 microgals obtained. The Hammond-Faller apparatus is not a field instrument, but it does provide a means for making precise absolute measurements at many points over the Earth.

Measurement with laser-based systems

Relative measurements. For studying Earth structures, instruments that will measure the differences in g from points where g is known are required. They have to be rugged enough to be taken into the field and capable of providing a reading in a matter of a few minutes. Instruments suitable for measuring g on ships at sea also are needed. As long ago as 1849, Sir John Herschel of England proposed an instrument consisting of a fixed mass m suspended on a spring. As the instrument was taken to different places, the varying weight mg of the mass produced differences in the extension of the spring. Yet, even for relative measurements, Herschel's instrument lacked the required sensitivity. Until about 1930 all relative gravity measurements as well as absolute measurements on the Earth were made with physical pendulums. When equation (20) is applied to two stations, 1 and 2, and l is the constant-equivalent simple pendulum length, the ratio of the values of gravity is immediately obtained in terms of the periods:

$$\frac{g_1}{g_2} = \frac{T_2^2}{T_1^2}. \qquad (22)$$

Pendulum measurements, however, are necessarily very time consuming, and the realization that variations in g could be utilized in oil exploration led to intensive research on improving the static gravimeter. The difficulties Herschel had encountered were overcome by choosing suitably stable material for the springs, by employing mechanical, electrical, or optical devices to amplify the small displacements of the system, and by providing temperature control or compensation.

Such improvements are very much apparent in the Worden gravimeter, an example of a modern, highly portable system. Gravimeters of this type weigh only a few pounds and can measure differences in g to about 0.01 milligal in a few moments. All such instruments, however, have two limitations. As a system ages, readings at a single station will change over and above the true tidal change of g. This instrumental "drift" must be corrected by arranging observations in closed circuits so that readings at base points are repeated. Second, all differences in gravity are obtained initially in arbitrary scale divisions. Consequently, the instruments must be calibrated by measuring differences between points where g is known.

Gravity measurements from ships and aircraft

When measurements of gravity are made on a moving ship or in an aircraft, new effects come into play, and these require the most careful consideration if useful results are to be obtained. The most important of these effects is the fluctuating vertical acceleration of the vehicle relative to the Earth; its instantaneous value cannot be separated from an instantaneous measurement of g. On a ship, for example, vertical accelerations of thousands of milligals are possible, even in times of moderate swell. To measure g to a precision of one milligal at first appears impossible, but averaging over time makes it possible to reduce the effect. If the instantaneous vertical acceleration of the vehicle is $\frac{d^2z}{dt^2}$, its average over a time interval T is

$$\frac{1}{T}\int_0^T \left(\frac{d^2z}{dt^2}\right) dt = \frac{1}{T}\left[\left(\frac{dz}{dt}\right)_T - \left(\frac{dz}{dt}\right)_0\right]. \qquad (23)$$

The quantity in brackets involves the vertical velocities of the vehicle at the beginning and end of the averaging interval. In some cases, this quantity can be measured using precise positioning techniques. Otherwise, the averaging interval T must be made sufficiently long for the quotient to be negligible. For ship-borne observations, recording gravimeters mounted on stabilized platforms to eliminate other disturbances are used in conjunction with computers to average the response over any adopted time interval T. The remaining problem, which is particularly serious in measurements from aircraft, is that there is a trade-off between accuracy and resolution. Only a single corrected value of g is obtained corresponding to the time interval T (which can be several minutes), and at aircraft speeds this would be an average over many kilometres of path. The second serious effect that arises in any measurement from a moving support is one pointed out early in the 20th century by the Hungarian physicist Roland Eötvös. Any body moving relative to the Earth experiences a centripetal acceleration different from that of a body at rest on the Earth, and since the centripetal term appears in g, the measured gravitational acceleration will be different for a moving observer. The so-called Eötvös effect reaches a value of approximately five milligals in middle latitudes for an east–west component of velocity of just 1.6 kilometres per hour. If gravity measurements accurate to one milligal are to be made, the most precise navigational systems are required. When these are available, shipborne surveys can be carried out with considerable success. The

airborne measurement of g remains experimental and appears to be limited to high-altitude surveys of a very general nature and low resolution. Some of the problems of measuring g from a moving vehicle are removed if, instead of g itself, the horizontal gradients of gravity are measured. Research is in progress on gradiometers that could be carried on aircraft or even on orbiting satellites.

For recording small tidal changes in gravity at a fixed site, a great advance has been made through the application of the low-temperature phenomenon of electrical superconductivity. In one gravimeter based on this phenomenon, a metallic sphere cooled by liquid helium to superconducting temperature is held in the constant magnetic field of superconducting coils. Changes in gravity tend to displace the sphere, but this is opposed by an electric field applied by capacitor plates above and below the sphere. The quantity recorded is the voltage that must be applied to these plates. Instruments of this kind measure variations in g to an accuracy approaching one microgal and have proved to be extremely valuable in the study of the tidal variations in gravity.

INTERPRETATION OF GRAVITY DATA

Isostasy. The general concept that higher portions of the Earth's crust are lighter and are maintained in position by correspondingly light roots beneath is very old. The quantitative description of this "compensation" of the Earth's topographic features dates from the geodetic triangulation of India in which the effect of the attraction of the Himalayas on the deflection of the vertical was accurately measured. In 1855 John Henry Pratt, an English amateur scientist, showed that the attraction was everywhere less than would be produced by the visible mass of the mountains. That same year the English astronomer George Biddell Airy offered the interpretation that the surface features of the Earth are formed in a crust whose density is less than that of the substratum; highly elevated regions of the Earth have crustal roots extending to greater depth (Figure 7). Pratt proposed an alternative model in which the density of crustal columns varies inversely with their height. In both cases, the weight of any crustal column of unit cross-sectional area exerted at the "level of compensation" is everywhere the same. Airy's description of his proposed mechanism was remarkable for the time because it preceded by more than 50 years the seismological identification of the crust and mantle (see below).

The Pratt and Airy proposals

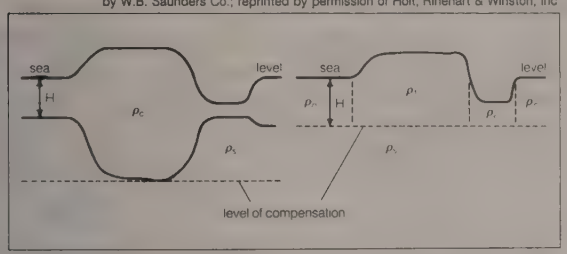

Figure 7: Airy's (left) and Pratt's (right) views of isostasy. In Airy's model, ρ_c is the constant crustal density; in that of Pratt, ρ_n is normal crustal density. The weight per unit area of all columns of the Earth is equal at the level of compensation.

The term isostasy was introduced in 1889 by the American geologist Clarence E. Dutton to describe the condition of equal pressure beneath a certain depth. During the early decades of the 20th century both the Pratt and Airy mechanisms were subjected to quantitative tests in which anomalies in the magnitude of gravity were first employed. Geodesists, led by John F. Hayford of the United States, tended to investigate the Pratt mechanism, while geophysicists, led by Weikko A. Heiskanen of Finland, concentrated on that of Airy. In both cases the approach was to compute new types of gravity anomalies known as isostatic anomalies, in which the effect of the roots on gravity, computed from the visible topography under the assumption of one or the other mechanism and model parameters (crustal thickness, densities), was added to the Bouguer anomaly. Model parameters were then varied until the closest approach to zero anomaly at all stations was obtained. In general, the best fit with the Pratt mechanism was achieved with a crustal thickness of about 100 kilometres, and with the Airy mechanism, a thickness of the crust for regions at sea level of 30–40 kilometres. The latter figures, in general agreement with the seismological thickness of the crust, supported the view that the Mohorovičić discontinuity (the interface between the crust and mantle) was the base of the Airy crust. With either model, there remain significant residuals that indicate local departures from the ideal isostatic condition.

As they stand, both the Pratt and Airy mechanisms are now known to be oversimplifications as compared with the real Earth. Yet, the ideas of Pratt and Hayford were to have an impact on the modern concept of plate tectonics (see below). The American geologist Joseph Barrell, analyzing their results, pointed out that the portion of the Earth above the level of compensation must be rigid (otherwise mountains would not stand up at all), and he dubbed this portion (apparently about 100 kilometres thick) the lithosphere and called the yielding region beneath the asthenosphere.

Isostatic compensation as a fundamental property

That some form of isostatic compensation is a fundamental property of the Earth can be seen in several ways: in the lack of expression of the continents and oceans in the global map of the geoid (Figure 4) and in the universal tendency of Bouguer anomalies to trend toward large negative values in elevated regions.

Modern investigations of isostasy on a statistical basis take as their starting point the correlation between Bouguer anomaly and height in regions of continental size. In such a region, both the Bouguer anomaly Δg and the topographic height h are Fourier transformed into functions of vector wave number k (*i.e.*, $|k| = 2\pi/\text{wavelength}$). Then, when there is correlation

$$\Delta g(k) = Q(k) \cdot h(k) + \text{residual}. \qquad (24)$$

Here $Q(k)$, measured in milligals per metres of height, is known as the isostatic response function, a term introduced by Leroy M. Dorman and Brian T.R. Lewis in a study of gravity over the continental United States undertaken during the early 1970s. A typical variation of $Q(k)$ with wavelength is shown in Figure 8. Since the Bouguer anomaly measures essentially the effect of the negative compensating masses, or roots, the form of the curve can be used to indicate their depth. For example, in the case of local Airy compensation, with the roots condensed onto a plane at depth z, the response function is

$$Q(k) = -2\pi\rho G \exp(-kz), \qquad (25)$$

where ρ is the crustal density.

The value of z may then be determined to best fit the observed response curve. The procedure may be generalized to cases where the compensation is distributed over depth and the response curve inverted to give the density deficiency as a function of depth. In most of the continental areas that have been analyzed, the compensating masses appear to be concentrated near the Mohorovičić discontinuity. This interface represents the main discontinuity in density in the outer part of the Earth (perhaps as much as 0.5 gram per cubic centimetre between lower crustal and mantle material). By contrast, the base of the lithosphere, which is marked by a change in mechanical

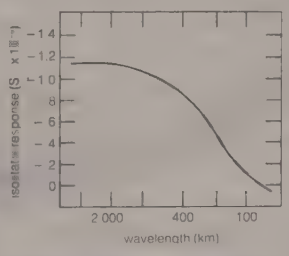

Figure 8: The isostatic response function (Bouguer anomaly per unit of topographic height) as a function of wavelength for a typical continental area.

rather than chemical properties, may have only a very small discontinuity in density associated with it.

In the light of current ideas on plate tectonics, a fundamental question is whether, with a rigid lithosphere, isostatic compensation exists on the local point-by-point basis visualized by Pratt and Airy. Should not the application of loads to the lithosphere cause it to flex gently as an elastic plate floating on a dense fluid? In the extreme case, even though most of the signal in the gravity anomaly is produced at the Mohorovičić discontinuity, that interface is passively warped into surfaces that parallel, and are determined by, the lithosphere as a whole. The isostatic response function $Q(k)$ can be expressed for this model also. In contrast to equation (25), it contains two model parameters: depth of compensation and flexural rigidity of the lithosphere. Various continental areas have been investigated using this model, with the result that very small values have been found for the thickness of the elastic lithosphere, often less than the depth to the Mohorovičić discontinuity, which is typically 35 kilometres beneath continents. For example, in the case of eastern North America, the method shows an elastic thickness of only 20 kilometres, much less than the lithospheric thickness of 50 to 100 kilometres suggested by seismic wave velocities. While it is conceivable that the effective thickness of "rigid" material is different for different time scales, the result contains a paradox. For if the roots are in the asthenosphere below the base of the lithosphere, there is no reason why they should not have disappeared by flow in the case of old topographic features. The solution seems to lie in the fact that the Mohorovičić discontinuity does not simply flex in a passive way when mountains and other relief features are formed. Horizontal forces fracture and thicken the crust by overthrusting, as shown in seismological profiles of the Himalayas. Compensation at the base of the crust is produced independently of lithospheric flexure, which itself is determined by the uncompensated, rather than total, topographic load.

The global significance of gravity anomalies. The investigations of isostasy described above are statistical in approach in that they are directed toward determining depth of compensation and lithospheric thickness from large data sets without reference to individual geologic structures. On the other hand, the study of gravity is capable of extending the understanding of such major features of global plate tectonics as mid-oceanic ridges and subduction zones. Just as plate tectonics itself began with a consideration of features of the ocean floors, it is the gravitational field over the oceans that is most diagnostic for these applications.

Subduction zones. It has been pointed out that, in comparison to magnetic and seismological studies, gravity measurements played only a secondary role in establishing the plate-tectonic theory in the 1960s. On the other hand, as early as 1929 the Dutch geophysicist Felix A. Vening Meinesz had shown that some of the most spectacular negative gravity anomalies on Earth are associated with oceanic trenches (Figure 9). These regions are now known to be subduction zones—*i.e.*, plate margins along which a slab of oceanic lithosphere is forced to descend beneath a continental plate. The narrow negative gravity anomalies result from the accumulation of light sedimentary material trapped between the plates. Not obvious on the map but more significant from the point of view of global tectonics is the extensive positive anomaly landward from the trough. These can be interpreted on the basis of a small positive density contrast between the descending slab and the surrounding normal mantle. Since the slab is similar chemically to its surroundings, the density contrast results from the lower temperature of the slab. Detailed analyses of the gravity field over subduction zones, in conjunction with seismic measurements, thus yield information on slab geometry, depth extent, and temperature.

Negative gravity anomalies

Mid-oceanic ridges. These structures represent the spreading axes of plate tectonics, along which hot volcanic material is ejected to become new oceanic lithosphere. Bathymetrically, the ridges are striking topographic features, rising one to three kilometres above the deep ocean floor on either side. That they are associated with geoidal highs can be seen on the global map of the geoid (Figure 4). On the average, however, the geoidal effect of such a ridge is moderate (Figure 10), indicating that some form of compensation is operative. Temperature variations in the oceanic plates moving away from the ridge axis appear to play a major role in the compensation. The ejected material is hot and therefore of low density. As the plates move apart, they lose heat vertically to the ocean above, cool, and become denser. If it is assumed that isostatic compensation is complete (it is a Pratt-type of isostasy), the profile of the ocean floor can be computed and is found to be in good agreement with the bathymetry. This lends strength to the cooling-plate model of ocean ridge topography. Nevertheless, if isostatic compensation is complete, why should there be a gravity high, or equivalently, a geoidal

Geoidal highs

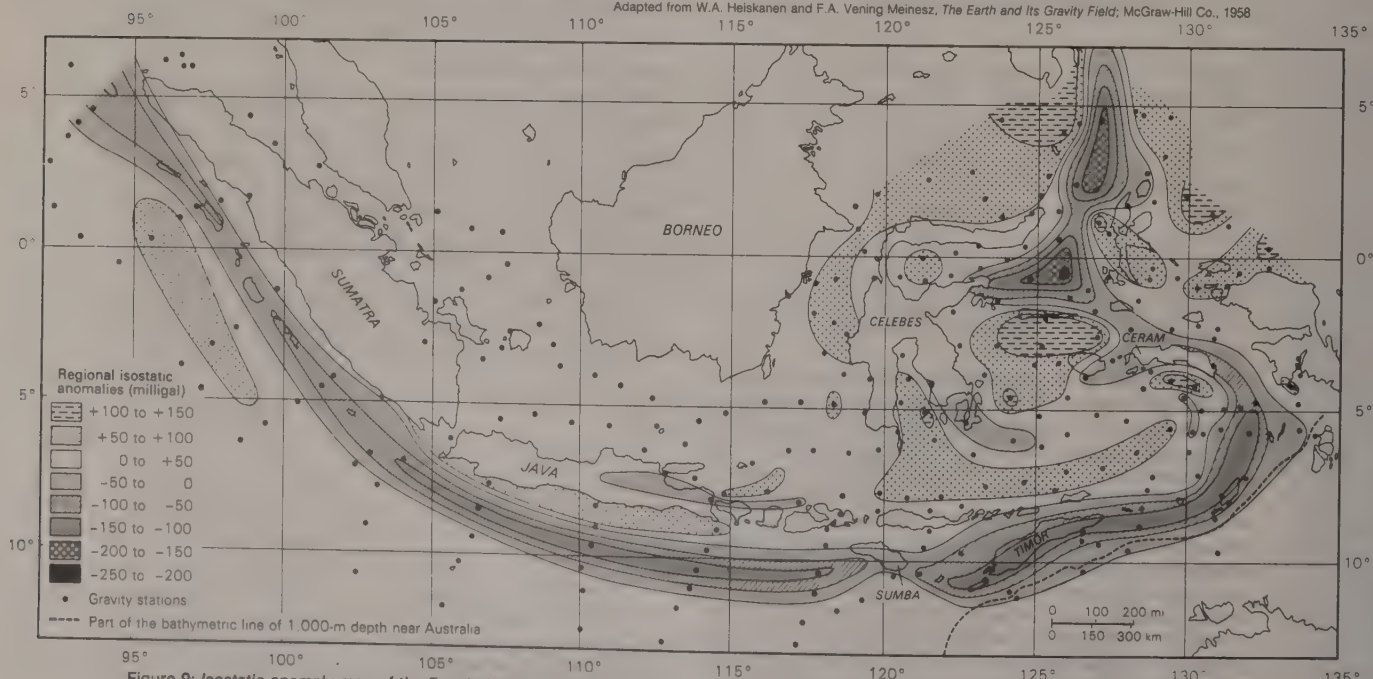

Figure 9: *Isostatic anomaly map of the East Indies.*
The dots indicate submarine gravity stations. For stations at sea, the free-air anomalies are not greatly different.

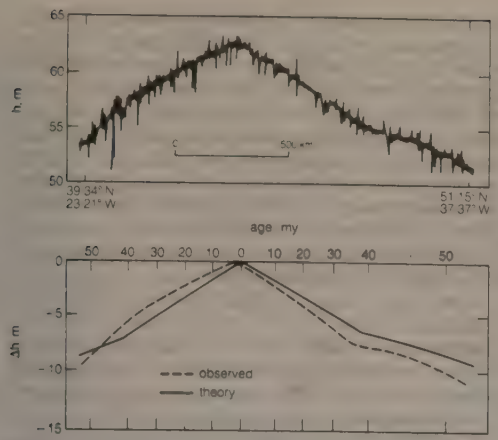

Figure 10: (Top) Observed geoidal profile across the Mid-Atlantic Ridge. (Bottom) The smoothed observed profile as compared with that calculated for spreading plates that are thermally compensated.

After W.F. Haxby and D.L. Turcotte, *Journal of Geophysical Research*, no. 83, p. 5475 (1978), copyright American Geophysical Union

high? The answer lies in the vertical separation between the positive masses (*i.e.*, the ridge itself relative to deep ocean) and the compensating "negative masses" that are distributed through the hot plates and therefore at greater depth. The result is similar to a "double layer" of opposite poles in magnetism. Positive gravitational potential is produced at the ocean surface, leading to the outward geoidal bulge. As Figure 10 indicates, both observations and model calculations indicate a geoidal height that decreases almost linearly with the age of the seafloor. The result is important for the interpretation of the oceanic geoid because it allows the effect of ridges to be removed so as to better display the effect of deeper structures.

There is another type of superficial feature that produces the small isolated circular highs readily visible on the geoid over the Pacific Ocean—namely, the seamount, or submarine volcanic cone, built on the ocean floor. As in the case of ridges, these features, though appearing to be compensated by plate flexure, produce geoidal highs because of the separation in depth of their masses and the compensation. Most interesting is the difference in signature between seamounts on young and older oceanic lithosphere. In the former case, the lithospheric plate has low flexural rigidity, and so it bends in such a way as it achieves more local compensation; the geoidal high is of small amplitude and is flanked by lows. On cold, stronger lithosphere, the compensation is of such regional extent that a pronounced geoidal high appears.

Mantle convection. Convection of mantle material, at velocities of centimetres per year, has been suggested as the driving force for plate motions, and it is natural to look for some expression of a system of mantle convection currents in the gravitational field. In a thermally driven convecting system, heated mantle material of lower density rises, moves horizontally dragging the lithosphere with it, and, after cooling, descends to complete the cycle. At first sight, one might expect that areas of rising currents would produce gravity lows because of the density deficiency, but in a system with a free upper boundary the convection currents themselves deform the boundary vertically, "piling up" material above rising currents. Model calculations show that in most cases this boundary effect predominates over the density variations in the material, leading to positive gravity or geoidal anomalies over rising currents and to negative ones over sinking currents.

While there is still no proof that mantle convection exists, there are gravity anomalies of intermediate-length scale that are suggestive of a system of convection cells. Figure 11 shows the geoid for the Pacific Ocean with short-wavelength features smoothed out. The effect of the East Pacific Rise has not been removed and appears as a high toward the lower right of the figure. Most striking, however, are the northwesterly alignments of alternating geoidal highs and lows (*e.g.*, D, T, G, V) extending in the direction of plate motion. The fact that these features of the geoid correlate positively with the bathymetry supports the suggestion that both result from some system of convection cells in the upper mantle.

Possibility of convection cells in the mantle

Areas of glacial depression and postglacial rebound. Prominent negative areas of the geoid (Figure 4) include Antarctica and northern North America centred over Hudson Bay. Both of these regions were covered with ice sheets during Pleistocene time (about 10,000 to 1,700,000 years ago), and it is believed the negative anomalies are related to a residual depression of the lithosphere that remained after the ice retreat. When an ice sheet develops on a continental area, compensation is provided by the downward deflection of the continental lithosphere, leading to outflow of the asthenospheric material beneath it. Melting of the ice leaves a depressed crust, which rebounds gradually as the viscous material flows back. During the period of rebound, the area will display a geoidal low and a negative free-air anomaly of a magnitude (over a broad region) of $2\pi G\rho y$, where ρ is the actual density of asthenospheric material (about 3.3 grams per cubic centimetre) and y is the distance that the Earth's crust must still rise. Gravity measurements thus yield values of y (it is roughly 200 metres for Hudson Bay). Taken in conjunction with the present-day rate of uplift, as given by repeated precise leveling, they allow the viscosity of the mantle material to be estimated.

Because these negative regions are near the poles, they contribute strongly to the term in J_2 in the potential (see above) and therefore to the flattening of the ellipsoid. Evidence exists from the perturbation of some satellite orbits—notably the orbit of the geodetic satellite Lageos—that J_2 is decreasing with time. There is a motion that cannot be explained by tidal or other known effects but that is consistent with a rate of decrease of J_2 of $\dot{J}_2 = -(26 \pm 6) \times 10^{-12}$ yr^{-1}. The fact that the flattening and therefore J_2 are decreasing with time is consistent with the upward motion of the previously glaciated polar regions. (G.D.G.)

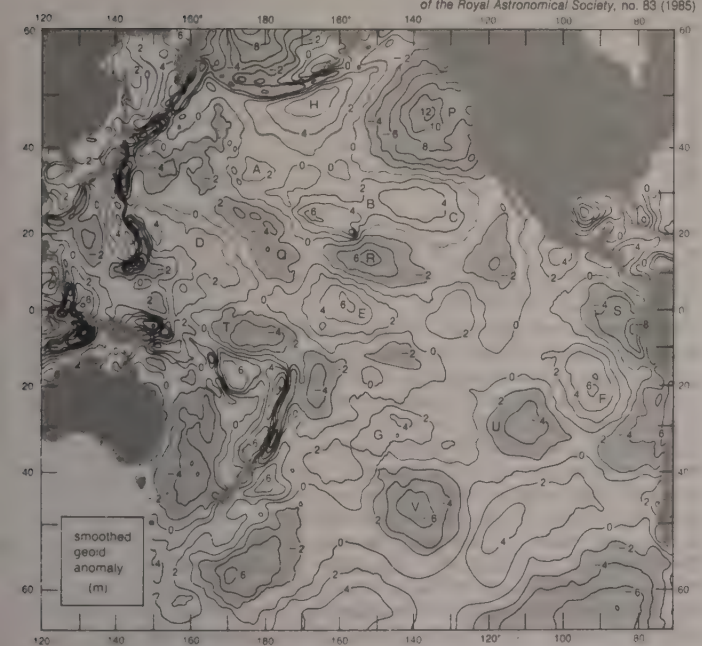

Figure 11: A smoothed geoid map of the Pacific Ocean. The intervals between contours are two metres. The shaded areas represent negative geoidal anomalies, and the letters indicate individual geoidal highs and lows.

The magnetic field of the Earth

The Earth's steady magnetic field is produced by many sources, both above and below the planet's surface. From the core outward, these include the geomagnetic dynamo, crustal magnetization, ionospheric dynamo, ring current,

magnetopause current, tail current, field-aligned currents, and auroral electrojets. The geomagnetic dynamo is the most important source because, without the field it creates, the other sources would not exist. Not far above the Earth's surface the effect of other sources becomes as strong or stronger than that of the geomagnetic dynamo. In the discussion that follows, each of these sources is considered and their respective causes explained.

Major disturbances of the main magnetic field

The Earth's magnetic field is subject to variation on all time scales. Each of the major sources of the so-called steady field undergo changes that produce transient variations, or disturbances. The main field has two major disturbances: quasi-periodic reversals and secular variation. The ionospheric dynamo is perturbed by seasonal and solar cycle changes as well as by solar and lunar tidal effects. The ring current responds to the solar wind (the ionized atmosphere of the Sun that expands outward into space and carries with it the solar magnetic field), growing in strength when appropriate solar wind conditions exist. Associated with the growth of the ring current is a second phenomenon, the magnetospheric substorm, which is most clearly seen in the aurora borealis. An entirely different type of magnetic variation is caused by magnetohydrodynamic (MHD) waves. These waves are sinusoidal variations in the electric and magnetic fields that are coupled to changes in particle density. They are the means by which information about changes in electric currents is transmitted, both within the Earth's core and in its surrounding environment of charged particles (see below).

OBSERVATIONS OF THE EARTH'S MAGNETIC FIELD

Representation of the field. Electric and magnetic fields are produced by a fundamental property of matter, electric charge. Electric fields are created by charges at rest relative to an observer, whereas magnetic fields are produced by moving charges. The two fields are different aspects of the electromagnetic field, which is the force that causes electric charges to interact. The electric field, **E**, at any point around a distribution of charge is defined as the force per unit charge when a positive test charge is placed at that point. For point charges the electric field points radially away from a positive charge and toward a negative charge.

A magnetic field is generated by moving charges—*i.e.*, an electric current. The magnetic induction, **B**, can be defined in a manner similar to **E** as proportional to the force per unit pole strength when a test magnetic pole is brought close to a source of magnetization. It is more common, however, to define it by the Lorentz-force equation. This equation states that the force felt by a charge q, moving with velocity $\boldsymbol{v}$, is given by

Lorentz-force equation

$$\boldsymbol{F} = q(\boldsymbol{v} \times \boldsymbol{B}). \qquad (26)$$

In this equation bold characters indicate vectors (quantities that have both magnitude and direction) and nonbold characters denote scalar quantities such as B, the length of the vector $\boldsymbol{B}$. The $\times$ indicates a cross product (*i.e.*, a vector at right angles to both $\boldsymbol{v}$ and $\boldsymbol{B}$, with length $vB \sin \theta$). Theta is the angle between the vectors $\boldsymbol{v}$ and $\boldsymbol{B}$. (**B** is usually called the magnetic field in spite of the fact that this name is reserved for the quantity **H**, which is also used in studies of magnetic fields.) For a simple line current, the field is cylindrical around the current. The sense of the field depends on the direction of the current, which is defined as the direction of motion of positive charges. The right-hand rule defines the direction of $\boldsymbol{B}$ by stating that it points in the direction of the fingers of the right hand when the thumb points in the direction of the current.

In the International System of Units (SI), the electric field is measured in terms of the rate of change of potential, volts per metre (V/m). Magnetic fields are measured in units of tesla (T). The tesla is a large unit for geophysical observations and a smaller unit, the nanotesla (nT; one nanotesla equals 10^{-9} tesla), is normally used. A nanotesla is equivalent to one gamma, a unit originally defined as 10^{-5} gauss, which is the unit of magnetic field in the centimetre-gram-second system. Both the gauss and gamma are still frequently used in the literature on geomagnetism even though they are no longer standard units.

Both electric and magnetic fields are described by vectors, which can be represented in different coordinate systems, such as Cartesian, polar, and spherical. In a Cartesian system the vector is decomposed into three components corresponding to the projections of the vector on three mutually orthogonal axes that are usually labeled x, y, z. In polar coordinates the vector is typically described by the length of the vector in the x-y plane, its azimuth angle in this plane relative to the x axis, and a third Cartesian z component. In spherical coordinates the field is described by the length of the total field vector, the polar angle of this vector from the z axis, and the azimuth angle of the projection of the vector in the x-y plane. In studies of the Earth's magnetic field all three systems are used extensively.

The nomenclature employed in the study of geomagnetism for the various components of the vector field is summarized in Figure 12. $\boldsymbol{B}$ is the vector magnetic field, and F is the magnitude or length of $\boldsymbol{B}$. X, Y, and Z are the three Cartesian components of the field, usually measured with respect to a geographic coordinate system. X is northward, Y is eastward, and completing a right-handed system, Z is vertically down toward the centre of the Earth. The magnitude of the field projected in the horizontal plane is called H. This projection makes an angle D (for declination) measured positive from the north to the east. The dip angle, I (for inclination), is the angle that the total field vector makes with respect to the horizontal plane and is positive for vectors below the plane. It is the complement of the usual polar angle of spherical coordinates. (Geographic and magnetic north coincide along the "agonic line.")

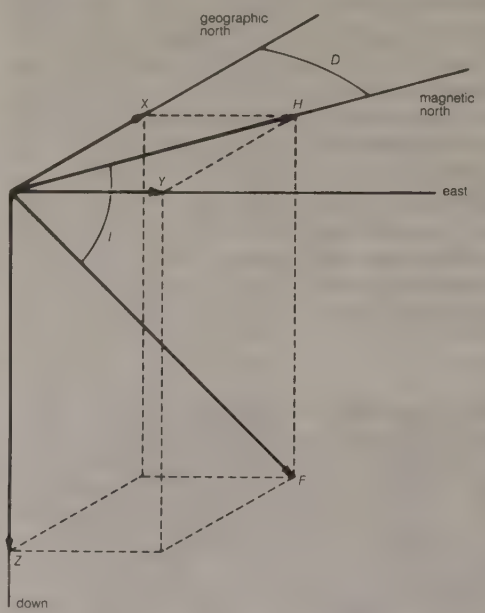

Figure 12: The components of the magnetic induction vector, $\boldsymbol{B}$, are shown in three coordinate systems—Cartesian, polar, and spherical.

Measurement of the field. Magnetic fields can be measured in various ways. The simplest measurement technique still employed today involves the use of the compass, a device consisting of a permanently magnetized needle that is balanced to pivot in the horizontal plane. In the presence of a magnetic field and in the absence of gravity, a magnetized needle aligns itself exactly along the magnetic field vector. When balanced on a pivot in the presence of gravity, it becomes aligned with a component of the field. In the conventional compass, this is the horizontal component. A magnetized needle may also be pivoted and balanced about a horizontal axis. If this device, called a dip meter, is first aligned in the direction of the magnetic meridian as defined by a compass, the needle lines up with the total field vector and measures the inclination angle I. Finally, it is possible to measure the magnitude of the horizontal field by the oscillations of the compass needle. It can be shown that the period

of such an oscillation depends on properties of the needle and the strength of the field.

Magnetic observatories continuously measure and record the Earth's magnetic field at a number of locations. In an observatory of this sort, magnetized needles with reflecting mirrors are suspended by quartz fibres. Light beams reflected from the mirrors are imaged on a photographic negative mounted on a rotating drum. Variations in the field cause corresponding deflections on the negative. Typical scale factors for such observatories correspond to 2–10 nanoteslas per millimetre vertically and 20 millimetres per hour horizontally. A print of the developed negative is called a magnetogram.

Magnetic observatories have recorded data in this manner for well over 100 years. Their magnetograms are photographed on microfilm and submitted to world data centres, where they are available for scientific or practical use. Such applications include the creation of world magnetic maps for navigation and surveying; correction of data obtained in air, land, and sea surveys for mineral and oil deposits; and scientific studies of the interaction of the Sun with the Earth.

Measurements with proton-precession and flux-gate magnetometers

In recent years, other methods of measuring magnetic fields have proved more convenient, and older instruments are being gradually replaced. One such method involves the proton-precession magnetometer, which makes use of the magnetic and gyroscopic properties of protons in a fluid such as gasoline. In this method, the magnetic moments of protons are first aligned by a strong magnetic field produced by an external coil. The magnetic field is then turned off abruptly, and the protons try to align themselves with the Earth's field. However, since the protons are spinning as well as magnetized, they precess around the Earth's field with a frequency dependent on the magnitude of the latter. The external coil senses a weak voltage induced by this gyration. The period of gyration is determined electronically with sufficient accuracy to yield a sensitivity between 0.1 and 1.0 nanotesla.

An instrument that complements the proton-precession magnetometer is the flux-gate magnetometer. In contrast to the proton-precession magnetometer, the flux-gate device measures the three components of the field vector rather than its magnitude. It employs three sensors, each aligned with one of the three components of the field vector. Each sensor is constructed from a transformer wound around a core of high-permeability material (*e.g.*, mu-metal). The primary winding of the transformer is excited with a high-frequency (~5 kilohertz) sine wave. In the absence of any field along the transformer axis, the output signal in the secondary winding consists of only odd harmonics (component frequencies) of the drive frequency. If, however, a field is present, it biases the hysteresis loop for the core in one direction. This causes the core to become saturated sooner in one half of a drive cycle than in the other. This in turn causes the secondary voltage to include all even harmonics as well as odd. The amplitude and phase of the even harmonics are linearly proportional to the component of the field along the axis of the transformer.

Modern magnetic observatories

Most modern magnetic observatories have both a proton-precession magnetometer and a flux-gate magnetometer mounted on granite pillars in nonmagnetic, temperature-controlled rooms. The outputs from the instruments are electrical signals, and they are digitized and recorded on magnetic media. Many observatories also transmit their data soon after acquisition to central facilities where they are stored with data from other locations in a large computer database.

Magnetic measurements are often made at locations remote from fixed observatories. Such measurements are commonly part of a survey designed to better define the Earth's main field or to detect anomalies in it. Surveys of this type are routinely carried out by foot, ship, aircraft, and spacecraft. For surveys near the Earth's surface the proton-precession magnetometer is almost always used because it does not need to be precisely aligned. Above the Earth's surface the main field decreases rapidly, and the need for precise alignment is less severe. Thus, flux-gate magnetometers are generally employed on spacecraft. Calculation of components of the vector field in a coordinate system fixed with respect to the Earth requires knowledge of the location and orientation of the spacecraft.

CHARACTERISTICS OF THE EARTH'S MAGNETIC FIELD

To a first approximation the magnetic field observed at the surface of the Earth is like that of a magnet aligned with the planet's rotation axis. Figure 13 shows such a field for a bar magnet located at the centre of a sphere. If the sphere is taken to be the Earth with the north geographic pole at the top of the diagram, the magnet must be oriented with its north magnetic pole downward toward the south geographic pole. Then, as shown in the diagram, magnetic field lines leave the north pole of the magnet and curve around until they cross the Earth's Equator pointing geographically northward. They curve still more reentering the Earth in northern latitudes, finally returning to the south pole of the magnet. At the present time, the north geographic pole corresponds to the south pole of the equivalent bar magnet. This has not always been the case. Many times in the history of the Earth the direction of the equivalent magnet has pointed in the opposite direction (see below *Reversals in the main field*).

Magnetic field lines

The magnetic field lines shown in the diagram are not real entities although they are frequently treated as such. A magnetic field is a continuous function that exists at every point in space. A field line is simply a means for visualizing the direction of this field. It is defined as a curve in three dimensions that is everywhere tangential to the local magnetic field. The pattern of field lines created by a bar magnet is called a dipolar field because it has the same shape as the electric field produced by two (di-) slightly separated charges (poles) of opposite sign. The dipole field of the Earth is, of course, not produced by a bar magnet at its centre. As will be discussed later, it is instead produced by electric currents within the Earth's liquid core. To produce the present field, the equivalent current must be a westward equatorial loop as shown in Figure 13. In SI units the dipole moment, μ, for the Earth is 7.95×10^{22} A/m^2 (amperes per square metre). Since $\mu = IA$ (current times area), a loop the size of the liquid core ($R_c = 3.48 \times 10^6$ m) would require an equivalent current of nearly 2×10^9 A.

It can be seen from Figure 13 that the magnetic field of a dipole is vertical along the polar axis and horizontal along the equator. These properties lead to definitions of equator and pole in the Earth's more complex field. Thus the geomagnetic equator is defined as the line around the Earth's surface where the actual field is horizontal. Similarly, the magnetic dip poles are the two points at which the field is vertical. If observations are extended above or below the surface, the location of the equator is a surface (planar for a dipole) and the poles lie along curves.

At a given distance in a pure dipole field, the polar field is always twice the equatorial field. The map in Figure 14 demonstrates that this is roughly true for the Earth's field. The map shows contours of constant total field magnitude according to a 1980 model plotted on a geographic

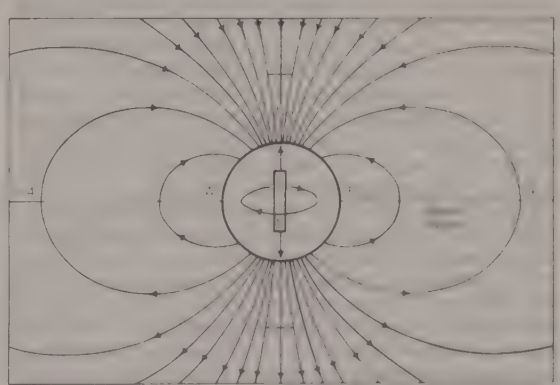

Figure 13: The magnetic field of a bar magnet has a simple configuration known as a dipole field. Close to the Earth's surface this field is a reasonable approximation to the actual field.

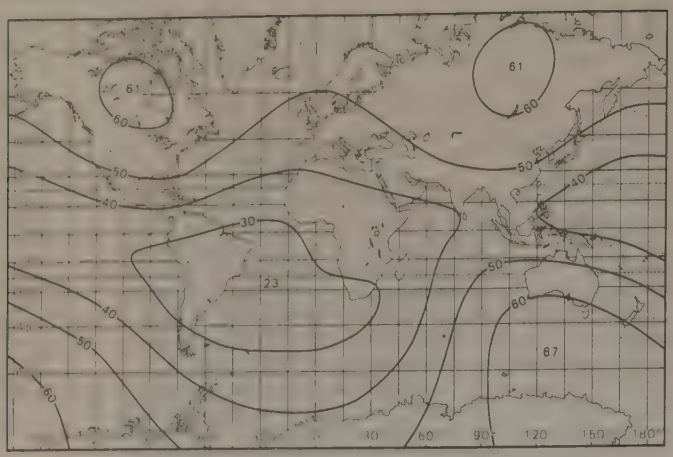

Figure 14: The total magnetic field measured on the Earth's surface shown by contours tracing locations of the constant total field. The data (from R.A. Langel *et al.*, 1980) are plotted on a geographic Mercator projection.

Mercator projection. The largest fields occur at two points in the Northern and Southern hemispheres not far from the geomagnetic poles. The weakest field occurs along the magnetic equator, with the lowest value being observed on the Atlantic coast of South America.

Several facts about the Earth's field are apparent from the total field map. First, the dipole approximating it is not exactly aligned with the rotation axis. The poles of the dipole are located roughly in northern Canada and on the coast of Antarctica rather than at the geographic poles. This implies that the dipole is tilted away from the rotation axis in a geographic meridian passing through the eastern United States. The exact tilt of the best centred dipole is 11° away from the geographic North Pole toward North America at a longitude 71° W of Greenwich. The total field map also suggests that the field is not exactly centred in the Earth, for if it were the field strength should be nearly constant along the Equator.

Relationship of the dipole to the geomagnetic poles

The mathematical description of a vector field on the surface of a sphere is quite complicated. In studies of the Earth's field it is usually done by multipole expansions. The field is assumed to be made of the superposition of fields from a series of poles located at the centre of the Earth. The first pole in this expansion is a monopole corresponding to only one pole of a magnet. Since no magnetic monopole has ever been observed, this term is not used. The next term is the dipole, then the quadrupole, and so forth. When the Earth's field is described in this manner, it is found that the dipole term accounts for more than 90 percent of the field. If the contribution from a centred dipole is subtracted from the observed field, the residual is called the non-dipole field, or regional geomagnetic anomaly.

Current maps of the regional anomaly for various components of the magnetic field show that there is a large maximum in the South Atlantic and in Mongolia. This anomaly can be partially explained by offsetting the best fit dipole in an appropriate manner. Anomalies such as this affect compass readings in polar regions and influence particles trapped in the outer field. They also are responsible for the separation between the locations of the dipole poles and the geomagnetic poles.

Magnetic surveys of the Earth's field have been conducted with increasing accuracy for well over 100 years. In recent times, they have been conducted on approximately a 10-year schedule. For each survey it is possible to define the dipole and non-dipole components of the field. It has been found that both change systematically with time. The nature of these changes and their probable explanations are discussed below in *Sources of variation in the steady magnetic field.*

In the multipole description of the Earth's field, it is shown that the effects of higher order poles decrease more rapidly with distance than those of the lower order poles. The field of a monopole, for example, decreases as the inverse square of distance, the dipole as the inverse cube, and so on. Because of this property, it might be expected that the outer portions of the Earth's field would be almost purely dipolar. Recent spacecraft observations, however, show that this is not true. The field departs radically from that of a dipole at altitudes of only a few Earth radii.

Surface observations do not suggest that significant distortion of the Earth's field should occur close to the planet. The technique of multipole expansion makes it possible to separate the observed surface field into parts of origin internal and external to the Earth. When surface observations are averaged over several years, less than 1 percent of the surface field is produced by external sources. Thus the existence of the external distortion is surprising.

Spacecraft determination of the Earth's outer field

The actual configuration of the Earth's outer magnetic field as recently determined by spacecraft is summarized in Figure 15. The diagram shows projections of magnetic field lines into the noon–midnight meridian at a time near an equinox. At this time the Earth's rotation axis is perpendicular to the Earth–Sun line. The dipole axis will be tilted another plus or minus 11°, depending on the time of day. On the dayside of the Earth, the magnetic field of the planet terminates at a distance of about 10 R_e (where R_e is the Earth's equatorial radius of about 6,378 kilometres). The boundary that exists at this point is called the magnetopause (break in magnetic field). Outside this boundary magnetic fields and particles are present, but they belong to the Sun's atmosphere and not to the Earth's. On the nightside, the magnetic field is drawn out into a long tail consisting of two lobes separated by a 14-R_e-thick sheet of particles called the plasma sheet. The plasma sheet has an inner boundary about 11 R_e behind the Earth. It also has upper and lower boundaries as shown. The projection of these boundaries onto the northern and southern portions of the atmosphere at about 67° magnetic latitude corresponds to two regions called the nightside auroral ovals. The aurora borealis and aurora australis (northern lights and southern lights) appear within the regions defined by the feet of these field lines and are caused by bombardment of the atmosphere by energetic charged particles. On the dayside, magnetic field lines from high latitudes split, some crossing the Equator, while others cross over the polar caps. The regions where the field lines split are called polar cusps. The projection of the polar cusps on the atmosphere at about 72° magnetic latitude creates the dayside auroral ovals. Auroras can be seen in these regions in the dark hours of winter, but they are much weaker than on the nightside because the particles that produce them have much less energy. The projections of the two lobes of the magnetic tail onto the atmosphere are the polar caps.

Within the middle of the Earth's field are several other important boundaries and regions that cannot be detected by magnetic field observations. Close to the Earth (1–2 R_e) is the inner Van Allen radiation belt, which consists

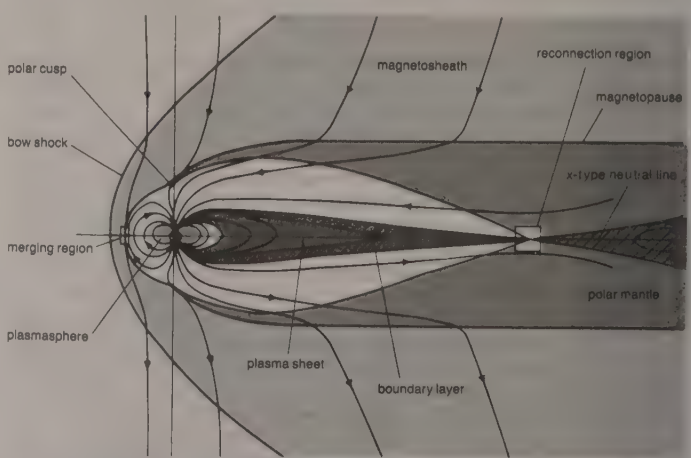

Figure 15: Field lines of the Earth's magnetic field are shown projected into the noon–midnight meridian plane. Major features of the Earth's magnetic field are labeled.

of very energetic particles created by cosmic rays. Centred at about 4–5 R_e is the outer Van Allen belt, created from charged particles of both solar and atmospheric origin. Also at this distance is the plasmapause. This is a boundary in the Earth's plasma (a relatively cold gas consisting of equal numbers of electrons and positive ions) and, as such, actually constitutes a boundary in the planet's electric field.

SOURCES OF THE STEADY MAGNETIC FIELD

The geomagnetic dynamo. Observations of the magnetic field of the Earth's surface indicate that more than 90 percent of this field arises from sources internal to the planet. A variety of mechanisms for generating this field have been proposed, but at present only the geomagnetic dynamo is seriously considered. In the dynamo mechanism, fluid motion in the core moves conducting material across an existing magnetic field and creates an electric current. This current produces a magnetic field that also interacts with the fluid motion to create a secondary magnetic field with the same orientation as the original field. The two fields together are stronger than the original. The additional energy in the amplified field comes at the expense of a decrease in energy in the fluid motion.

Dynamo mechanism

Thermal heating in the core is the process that drives fluid motion. For many years it was thought that this heating was caused by radioactive elements dissolved in the liquid core. Recent work suggests that freezing of the liquid core is more important. Seismic studies have shown that the centre of the Earth is a solid sphere of iron with an approximate radius of 1,200 kilometres. This sphere is surrounded by an outer core of liquid iron. With time, the inner surface of the liquid core freezes onto the outer surface of the solid core. Energy released in the freezing process heats the surroundings to a high temperature. The heat flows in all directions, raising the temperature of adjacent regions. Because heat cannot be lost from the interior, it eventually flows to the surface. There, it is radiated into the cold of space as infrared radiation. This process establishes a radial temperature distribution that decreases toward the surface. If heat is generated too rapidly for conduction to carry it away, a second process, convection, becomes important. In convection, energy is transported by bubbles of hot fluid that rise toward cooler regions carrying more heat than flows through the same material at rest.

Several conditions must be satisfied for the fluid motion to produce a magnetic field. First, the fluid must be electrically conducting. Second, a magnetic field must be present, possibly as a relict of the initial formation of the body. Third, some force must introduce twists into the fluid motion so that the initial magnetic field becomes distorted by the motion. For the Earth, liquid iron is conducting, an initial magnetic field is likely, and the Coriolis force introduces twists. The Coriolis force is the force felt by a fluid in or on a rotating body. It is the force that creates cyclonic storms in the Earth's atmosphere, and in the Northern Hemisphere it causes a fluid rising radially to rotate counterclockwise.

Generation of a self-sustaining magnetic field

The example presented in Figure 16, designated the $\alpha\omega$ dynamo, illustrates how these factors might generate a self-sustaining magnetic field. Assume first (A) that there is present an initial poloidal magnetic field (one lying in meridian planes). Suppose next that the innermost part of the field line is embedded in a fluid rotating more rapidly than the outer parts of the fluid. In good conductors, magnetic field lines are nearly frozen into the fluid and have to move as the fluid moves. After many rotations a field line will "wrap up" around the rotation axis, creating a large toroidal field (one lying in planes perpendicular to the rotation axis). Since the conductivity is not perfect, the toroidal loop may diffuse through the fluid, disconnecting itself from the original poloidal field (B). This process is called the omega effect because it depends on the rotational velocity of the fluid.

Next, consider the effect of radial fluid motion on the toroidal field. At various points in the liquid core, fluid is rising in cells driven by thermal convection. The rising fluid carries with it the toroidal magnetic field. As it rises, the Coriolis force deflects the fluid and causes it to spin around the central axis of the cell, thereby twisting the magnetic field. After a rotation of about 270° the magnetic field lines begin to twist about themselves and can diffuse through the conductor, disconnecting from the toroidal loop (C). At this stage, the rising loop is oriented in a meridian plane with the field pointing in the same direction as the original field—*i.e.*, poloidal. This process is called the alpha effect (because the effects are proportional with constant, α, to the background field). Finally, small loops may merge into a single large loop, recreating the initial poloidal field (D). In cells of sinking fluid, the toroidal field wraps in the opposite direction and the poloidal loops have the opposite polarity. If the sinking process were exactly symmetrical, field loops produced in this manner would cancel loops created by rising fluid. Thus, for the process to create a net field of the correct sign, loops produced by sinking fluid must be weaker than loops resulting from rising fluid.

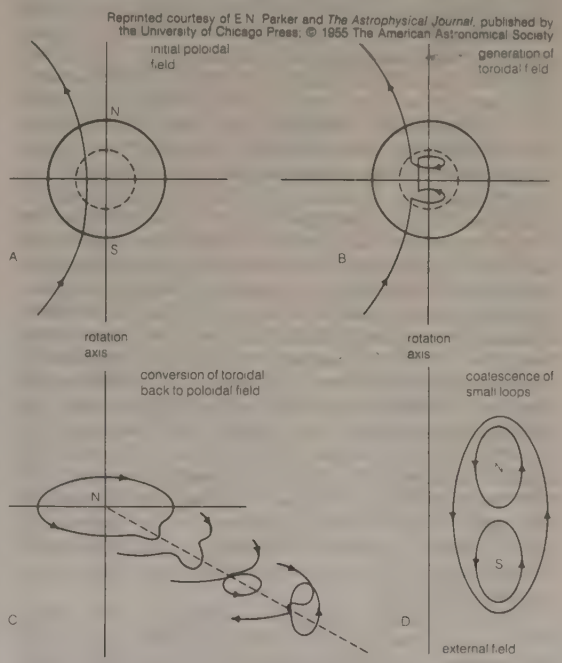

Figure 16: Generation of a self-sustaining magnetic field might be accomplished by this sequence of processes called the $\alpha\omega$ dynamo.

As discussed above, the simplest possible poloidal magnetic field is dipolar. Such a field could be produced by a single loop of electric current circulating around the Earth's rotation axis in the equatorial plane. The slight electric resistance of the conducting Earth, however, would long ago have dissipated this current if it were not continuously regenerated. As the illustration makes clear, this generation process is complex and depends on both radial motion and rotation of the fluid core.

Crustal magnetization. Magnetic fields measured at the Earth's surface are not entirely produced by the internal dynamo. Radially outward from the Earth's core, the next major source of magnetic field is crustal magnetization. The temperature of the materials constituting the crust is cool enough for them to exist in solid form. The solids may become magnetized by the Earth's main field and cause detectable anomalies.

Induced and remanant magnetization

Crustal magnetization is of two types: induced and remanant. Induced magnetization occurs when the elementary magnetic dipoles of crustal materials are aligned by the Earth's main field, just as a compass needle is aligned. If a material of particularly high susceptibility to magnetization is concentrated, as in a mineral deposit, it also can be approximated as a bar magnet that creates a small dipole field. On the scale of such concentrations, the Earth's main field is uniform, so, depending on an observer's location relative to the small dipole, its field may either add to or subtract from the main field. Because induced magnetiza-

tion is proportional to the strength of the inducing field, it vanishes when the primary field vanishes.

Remanant magnetization is similar to induced magnetization in that it is produced in a material by a primary field, but once created it persists after the primary field has disappeared. The phenomenon depends on the presence of ferromagnetic materials that form "magnetic domains," regions of aligned dipoles held in place by interatomic forces. In the Earth's crust, most remanant magnetization is created by trapping the dipole alignment of the Earth's main field as molten rocks harden.

The ionospheric dynamo. Above the Earth's surface, the next source of magnetic field is the ionospheric dynamo—an electric current system flowing in the planet's ionosphere. Beginning at about 50 kilometres and extending above 1,000 kilometres with a maximum at 400 kilometres, the ionosphere is formed primarily by the action of sunlight on atmospheric particles. There, sunlight strips electrons from neutral atoms and produces a partially ionized gas (plasma). On the dayside of the Earth near local noon and near the subsolar point, the Sun heats the ionosphere to high temperatures and causes it to flow away from noon toward midnight in a roughly radial pattern. The flow moves both neutral atoms and charged particles across the Earth's magnetic field lines. The Lorentz force discussed earlier causes the charges to be deflected in opposite directions perpendicular to the velocity of the charges and also the local field. This charge separation creates an electric field that also exerts a force on the charged particles. The form of the resulting electric field distribution is strongly dependent on the distribution of ionospheric conductivity and magnetic field. It is generally assumed, for example, that there is little ionospheric conductivity on the nightside and hence no current can flow there. As for the magnetic field, it points upward in the Southern Hemisphere, horizontally northward at the Equator, and downward in the Northern Hemisphere. The horizontal component of the magnetic field exerts a vertical force on charges that move as a result of winds. At the Equator this causes the positive and negative charges to be deflected vertically and produces a strong vertical electric field that impedes further separation of the charges. At higher magnetic latitudes, the magnetic field is primarily vertical and the deflections are horizontal, producing horizontal electric fields.

Complexity of the ionospheric dynamo current system

In general, charges separated by mechanical or chemical forces, as in dynamos or batteries, will discharge if there is an external electrical conductor through which they can flow. At high and low latitudes this process occurs in the same medium that generates the charge separation. The actual current path is particularly complex in the ionosphere because the electrical conductivity is spatially inhomogeneous and anisotropic—*i.e.*, it varies from point to point and has different values in different directions relative to the magnetic and electric fields present.

The form of the electric currents flowing in the ionosphere has been deduced from ground observations of daily variations in the magnetic field. On magnetically quiet days the field is observed to change in a systematic manner dependent primarily on local time and latitude. This variation has been dubbed the solar quiet-day variation, S_q. The magnetic variations can be used to deduce an equivalent electric current system, which, if flowing in the E region of the ionosphere, would produce the observed changes. This system is shown in Figure 17 for the equinoctial conditions of equal illumination of both hemispheres when the pattern is symmetrical about the Equator. The pattern consists of two current vortices circulating about foci at + and −30° magnetic latitude. Viewed from the Sun, circulation is counterclockwise in the Northern Hemisphere and clockwise in the Southern Hemisphere. Approximately 500,000 amperes flow eastward parallel to the Equator between the two foci. Apart from small changes brought about by daily rotation of small anomalies in the main field, the current and its effects at a fixed point in space are nearly steady. A magnetic observatory, however, rotates beneath different parts of the current system and records a time-varying magnetic field.

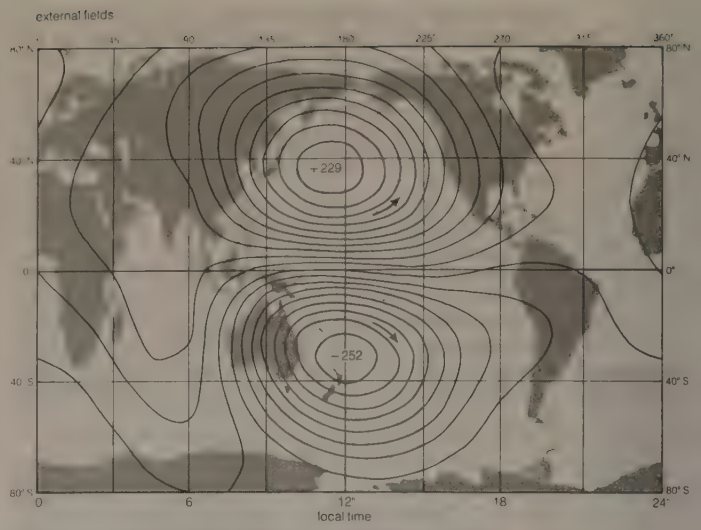

Figure 17: The ionospheric dynamo current system as seen from the Sun at an equinox. The contour lines are at intervals of 24.5 kiloamperes.

From W.D. Parkinson, *Introduction to Geomagnetism*, Scottish Academic Press Ltd (1983), reproduced with permission of the director, Bureau of Mineral Resources, Geology and Geophysics, Canberra

A detailed analysis of the daily variation reveals that several important factors contribute to the ionospheric wind system driving the dynamo. The most significant of these is the solar heating of the atmosphere discussed above. There is, however, a semidiurnal component caused by solar gravity that is roughly half as large as the diurnal component. As in the oceans, the tidal effect of gravity produces peaks in pressure at midnight as well as at noon. The resulting winds are more complex than is the case for the diurnal component. Similarly, there is a semidiurnal lunar component driven by lunar gravity. This variation is named the lunar daily variation, L. Its peak-to-peak amplitude is about $1/20$ that of S_q.

The ring current. Farther out, at 4 R_e and beyond, is the next major source of magnetic field, the ring current. At this distance almost all atmospheric particles are fully ionized and, hence, subject to the effects of electric and magnetic fields. Furthermore, the density of the particles is so low that the time between collisions may be many days or months. Here, energetic charged particles tend to behave independently rather than as part of a fluid. The behaviour of these particles may be approximated by the superposition of three types of motion, as shown schematically in Figure 18. These types include gyration about the

Particle motions

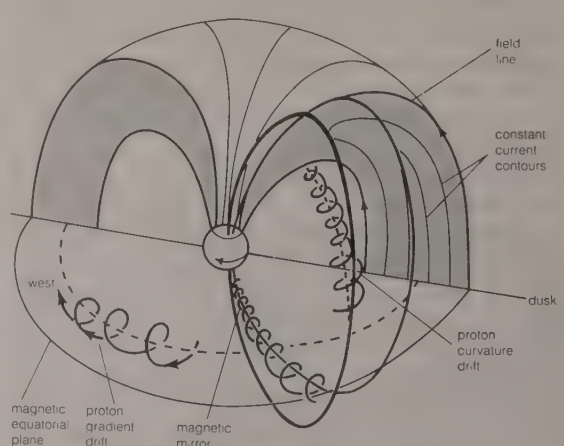

Figure 18: The motion of single particles in the Earth's magnetic field may be approximated by the superposition of their gyration about the main field, "bounce" along the field lines, and azimuthal drift in rings around the Earth. The trajectories of individual particles in the ring current fill a doughnut-shaped volume of space. The current produced by the particle drift causes a decrease in the surface field (see text).

main field, "bounce" along field lines, and azimuthal drift in rings around the Earth.

Gyration is caused by the Lorentz force, which makes charged particles move in circles around magnetic field lines. Reflection of particles at the ends of field lines is produced by the converging geometry of a dipole field. As a gyrating charged particle approaches the Earth moving along a field line, the particle encounters a magnetic mirror that reflects it. The mirror force is a component of the Lorentz force antiparallel to the motion of the particle when field lines converge.

Azimuthal drift is produced by two effects: a decrease in the strength of the main field away from the Earth, and a curvature of magnetic field lines. The first effect is easy to understand by considering the dependence of the particles' radius of gyration on the strength of the magnetic field. Strong fields cause small orbits. When a particle gyrates in the Earth's field, it has a larger radius close to the Earth than it does farther away. The projection of such motion into the equatorial plane is a cycloidal trajectory in a ring around the Earth rather than a simple circle around a local field line. Particles of opposite charge drift in opposite directions because their sense of gyration about the direction of the magnetic field is opposite—*i.e.*, protons gyrate in a left-handed sense (left handed with respect to the Earth's rotation axis) and drift westward, while electrons gyrate in a right-handed sense and drift eastward. Because the particles drift in opposite directions, they produce an electric current in the same direction as the proton drift.

A second cause of azimuthal drift known as curvature drift is also depicted in Figure 18. Particles with velocity nearly parallel to a field line at the Equator will initially move along the field line. Very soon, however, the field line curves away from the direction of particle motion. When this happens, there is a finite angle between the field and particle velocity, and the particle experiences the Lorentz force. For protons, this force is azimuthally westward, causing them to begin drifting in this direction. Now, however, there is a finite angle between the westward drift velocity and the field that creates a Lorentz force earthward. This force bends the trajectory of the particles along the field line. Together, the components of particle velocity along a field line and transverse to it cause the drift phenomenon in question.

A collection of charged particles trapped in the Earth's inner magnetic field and drifting as described above constitutes a Van Allen radiation belt. The current produced by this drift causes a magnetic field at the Earth's surface similar to that of a large ring of current in the planet's magnetic equatorial plane. Because the Earth is small compared with the size of this ring, the field is nearly uniform over the planet's surface. Its effect is to reduce the strength of the surface field. Actually, the particle drift is not confined to the equatorial plane, and the currents fill a doughnut-shaped volume defined by the shape of dipole field lines (Figure 18).

The magnetopause current. Farther still from the Earth, at about 10 R_e along the Earth–Sun line, is yet another current system that affects the surface field and profoundly changes the nature of the Earth's field in space. This system is called the magnetopause current, or Chapman-Ferraro current system after the English physicist Sydney Chapman and his student V.C.A. Ferraro who first suggested its existence. It flows in a single sheet and forms a boundary between the magnetic fields of the Earth and solar wind. When solar wind particles encounter the Earth's field, they are bent from their paths by the Lorentz force. As noted above, protons gyrate in a left-handed sense around a magnetic field and electrons in a right-handed sense. Since the particles are coming from the Sun and the direction of the Earth's field is upward parallel to its rotation axis, this gyration creates an electric current eastward in the equatorial plane as shown in Figure 19. The field of this current is such that it decreases the Earth's field outside the boundary and increases it inside. Once the current is fully developed, it occupies a thin sheet everywhere on the dayside of the Earth, outside of which is canceled all of the terrestrial field. Inside the sheet, the field is twice that of the main field.

Chapman-Ferraro current system

The magnetopause current system must close in some manner. More detailed consideration reveals that it closes on the magnetopause in much the same pattern as the dynamo currents in the ionosphere below. Figure 19 also presents a perspective view of the northern portion of the magnetopause current as seen from above the ecliptic plane. As indicated in the diagram, the current flows eastward across the dayside of the Earth and then westward around a "neutral point" (so called because the total field is nearly zero at this location). The current is symmetrical about the equatorial plane and encloses a volume of space known as the magnetosphere. Were it not for other processes (see below), the Earth's field would be completely contained inside the magnetopause. If the solar wind were absent, the field would expand indefinitely outward and produce the very simple dipole field illustrated in Figure 13.

The magnetotail current. Radially outward near local midnight rather than at local noon, there is an entirely different current system. Beginning at approximately 10 R_e and extending well beyond 200 R_e is the tail current system. This current is from dawn to dusk in the same direction as the ring current on the nightside of the Earth. In fact, it is produced by the same mechanism except that, in this region of space, curvature drift is the dominant cause of particle motion. Also, the Earth's field in this region is no longer even approximately dipolar, so the particle drift is nearly perpendicular to the Earth–Sun line rather than azimuthal around the Earth's centre. As in the case of the dayside magnetopause current, this current also closes on the magnetopause. In fact, above and below the Earth it is indistinguishable from the Chapman-Ferraro current because it closes in the same direction and is produced by the same mechanism of charge deflection. The tail current differs from the magnetopause current because over part of its path it flows interior to the Earth's magnetic field. In Figure 15 the region where this occurs is labeled the plasma sheet. For an observer on the nightside of the Earth looking away from the Sun, the current would appear to flow in a pattern similar to the Greek letter "theta." It flows westward (dawn to dusk) through the plasma sheet

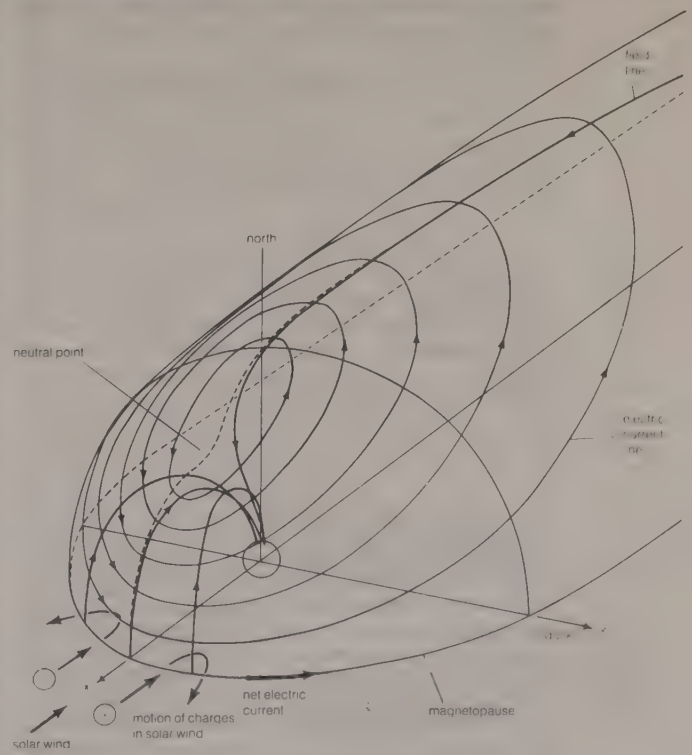

Figure 19: A perspective view of the northern portion of the magnetopause current, as seen from above the ecliptic plane. Charged particles in the solar wind are deflected in opposite directions by the Earth's main field, creating a boundary current. This current confines the field inside a finite volume called the magnetosphere (see text).

and then splits, closing above and below on the boundary of the magnetopause. Repetition of this current pattern continuously down the tail produces a current system that is essentially that of two long solenoids squashed together in a "theta" pattern, with opposite currents in the two solenoids.

Although the tail current is explained by the particle drifts discussed above, it is not obvious what process creates the tail-like magnetic field configuration required for these drifts. The Chapman-Ferraro current and the ring current are both produced in regions where the Earth's field is strong and dominated by the effects of the internal dynamo. Far from the Earth the field is stretched out into two long bundles of magnetic field lines confined by and almost wholly produced by the tail current system described above. In simplest terms, the particles travel in a field produced by their own movement. Particle motion of this type is another consequence of the interaction of the solar wind with the Earth's main field.

Effects of solar wind interaction

In the single-particle description of the solar wind interaction with the dayside magnetic field, it was noted that solar wind particles are deflected by the field and produce a current. This same interaction may be described in a fluid picture by stating that a boundary exists at a point where the magnetic pressure of the Earth's field exactly equals the perpendicular pressure of the solar wind on the boundary. On the dayside this is caused primarily by the velocity of the solar wind and not its thermal pressure.

The second component of the solar wind interaction is tangential drag, which is a frictional force exerted by the solar wind parallel to the boundary. The effect of this force is to move the Earth's field lines tailward. Two mechanisms are thought to be primarily responsible for tangential drag at the magnetopause. The first is called the viscous interaction and the second, reconnection. The latter is more difficult to visualize and will be discussed below in the section *Sources of variation in the steady magnetic field.* Both processes are summarized schematically in Figure 20.

Viscous interaction

Viscous interaction involves the transfer of momentum from the solar wind to a closed field line of the Earth's magnetic field just inside the boundary. Because of the transfer, a field line inside the boundary moves in the same direction as the solar wind. (An example of how such a transfer might occur is shown by the process of scattering a solar wind particle inside the magnetopause.)

The viscous interaction is capable of moving closed field lines from the dayside of the Earth far out on its nightside. Eventually the field lines become highly stretched into two oppositely directed bundles much like the tail of a comet except that the Earth's field is invisible. Tension in the field, combined with weakening of the tangential drag, allows the field line to return earthward. The field lines cannot return along the same path. Instead, they return through the interior of the Earth's field. The motion of these closed field lines in two closed loops, as shown in Figure 20, is called magnetospheric convection. This mechanism, together with the more important one due to reconnection, produces the tail current system.

The superposition of the Earth's main field, ring current, magnetopause current, and tail current produces a configuration of magnetic field lines quite different from that of the dipole shown in Figure 13. On the dayside the field lines are compressed inside a boundary located typically at 10 R_e. On the nightside the field is drawn out to distances probably exceeding 1,000 R_e. As will be discussed below, several processes interior to the magnetopause produce other boundaries besides the magnetopause. Several of these are evident from the Earth's surface as regions in the ionosphere within which specific types of auroras occur.

Field-aligned currents. Circulation of magnetic field lines in a pattern of closed loops within the magnetosphere is a consequence of the tangential drag of the solar wind. This circulation produces another important magnetic field source, the field-aligned current system. The field-aligned currents flow on two shells completely surrounding the Earth (Figure 21). The higher latitude shell is usually referred to as Region 1 and the lower one as Region 2. These two current sheets are caused by different physical mechanisms, but they are connected through the ionosphere and form a single circuit.

Region 1 current system

As can be seen from Figure 21, the Region 1 current originates in the region of the interface between field lines dragged tailward by the solar wind and field lines returning to the dayside of the Earth. This interface is electrically charged, positive on the dayside of the Earth and negative on the nightside. The charge on this interface is a consequence of the Lorentz force. Positive charges attached to field lines moving tailward on the dawn side of the Earth are deflected earthward toward the interface. In contrast, positive charges moving sunward just inside the interface are deflected away from the Earth (because their velocity is opposite to those on the other side of the interface). This is again toward the interface, hence a positive charge accumulates. On the dusk side the deflections are the same, but a negative charge accumulates at the interface. Because of this charge, the centres of the loops become charged like the terminals of a battery.

In the Earth's field, magnetic field lines are almost perfect conductors of current as there are no collisions to cause resistance. This allows the effects of the charge separation in the magnetosphere to be connected to the ionosphere at the feet of the charged field lines. Because the ionosphere conducts current, current can flow from the positive to negative terminals. Thus, current leaves the positive terminal of the magnetospheric "battery" and flows down field lines on the dawn side, then across the polar ionosphere, and finally out on the dusk side.

The actual current path is not nearly so simple because the ionospheric conductivity is not uniform. One source of nonuniformity is solar illumination of the dayside. Another is loss of particles from the magnetosphere to the ionosphere. This loss occurs in two rings centred around the north and south magnetic poles. Inside of these rings the ionosphere is constantly bombarded by particles that ionize the atmosphere and generate auroras. Because auroras are almost always present in these ovals, they are usually referred to as auroral ovals.

On the dayside, the particle bombardment is a result of the neutral points about which the magnetopause currents flow. These neutral points are natural funnels that allow solar wind particles to pass through the magnetopause.

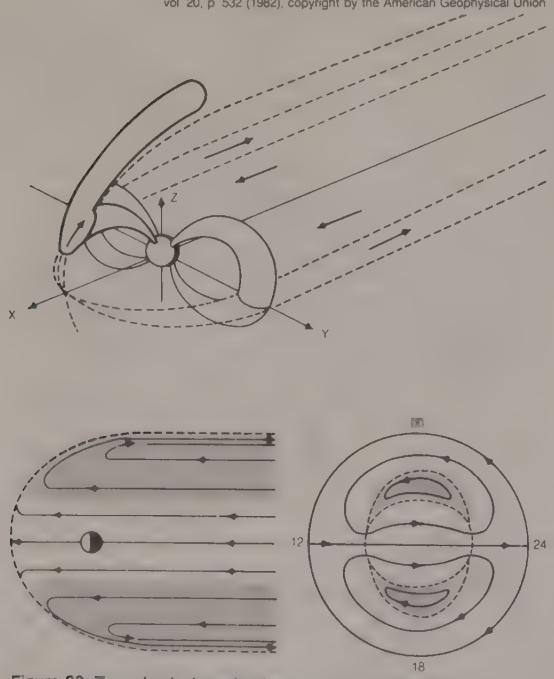

Figure 20: Two physical mechanisms create tangential drag on the outer boundary of the magnetosphere: viscous interaction and magnetic reconnection. The viscous interaction drags closed field lines along the flanks (bottom left), and magnetic reconnection transports open field lines over the poles (bottom right).

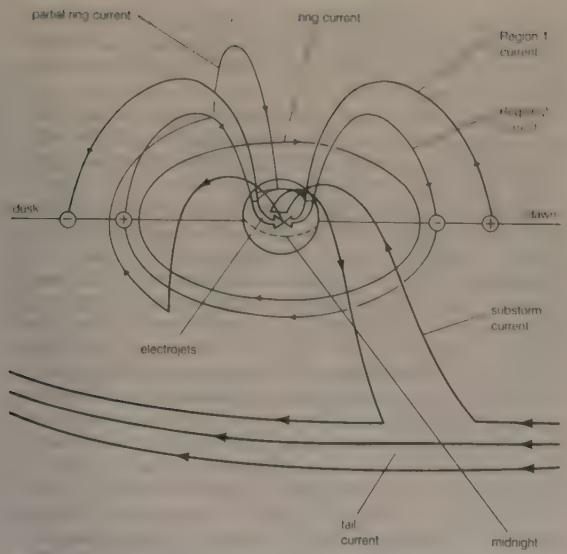

Figure 21: The field-aligned current system includes two shells of magnetic field lines connecting the magnetosphere to the ionosphere.

On the nightside the particles also originate in a natural funnel but, in this case, one produced by the projection of the plasma sheet onto the ionosphere. The particle bombardment increases the electrical conductivity of the ionosphere inside the auroral ovals relative to that in the surrounding ionosphere.

Region 2 current system

To understand the closure of the Region 1 current system, the Region 2 system must be considered. This second system is a result of charge separation by drift in the main field. As discussed in relation to the ring current, negative charges (electrons) drift eastward (in a right-handed sense) around the Earth, while positive charges (protons and heavy positive ions) drift westward. These particles preferentially approach the Earth on the nightside because of the magnetospheric convection system. As they approach the Earth, they tend to separate due to drift, with more negative charges drifting around the Earth on the dawn side and more positive charges around the dusk side. The centres of these regions also become electrically charged. Because field lines connect the regions to the ionosphere, currents can flow from them as well. In this case, the polarity is reversed from that of Region 1. Accordingly, in Region 2, current is drawn from the ionosphere on the dawn side and expelled to the magnetosphere on the dusk side.

The field-aligned current system shown in Figure 21 is a superposition of all the elements discussed above. The path of this current can be summarized as follows. Current leaves the region of interface between counterstreaming magnetic field lines on the dawn side and flows down all field lines lying in a volume connected to this region. The current then splits, some flowing across the illuminated portion of the polar cap and some flowing equatorward across the morning side of the auroral oval. The current that turns equatorward flows out along lower latitude field lines connected to the accumulation of negative charges and then flows westward across midnight as a partial ring current carried by the oppositely drifting particles. Near dusk it flows down along field lines to the ionosphere, then poleward, and finally out along field lines to the dusk interface.

At the dawn and dusk magnetopause, particles of opposite sign undergo certain actions. For example, at dawn negative charges are pushed outward toward the flowing solar wind. At dusk the opposite occurs. These charges also can discharge via field lines connected to the Earth in the region near the feet of field lines emanating from the dayside neutral points or perhaps through the solar wind by mechanisms not yet completely understood. This closure completes the electric circuit.

A surprising characteristic of the field-aligned current system is that its effects are almost completely invisible on the ground, even though it profoundly changes the field in space. Because the field-aligned current system consists of two oppositely directed, nearly parallel current sheets, its magnetic field is almost entirely confined between the sheets. The existence of this system is, however, apparent in one way. It drives a secondary ionospheric current system consisting of two convective electrojets.

Structure of the field-aligned current

Convective electrojets. The auroral electrojets are two broad sheets of electric current that flow from noon toward midnight in the northern and southern auroral ovals. The dawn side current flows westward, creating a decrease in the magnetic field on the surface. The dusk side current flows eastward and produces an increase in the magnetic field. Both currents flow at an altitude of approximately 120 kilometres in a region known as the E region of the ionosphere. In this region the collision rate between positive ions and atmospheric neutral particles is much larger than it is between electrons and neutrals. Higher in the ionosphere there are almost no collisions, while in the lower region there is little ionization. Because of the different collision rates, ions in the E region drift more slowly than electrons and thus create an electric current. At higher altitudes where equal numbers of positive and negative charges drift at the same rate, no current is produced because no net charge is transported. In the E region positive charges moving backward relative to the drift create a current opposite to the drift.

The ionospheric drift results from magnetospheric convection. Field lines with "feet" in the auroral ovals drift toward the dayside, so that the electrojet currents are toward the nightside. The electrojet currents flow at right angles to the sheets of ionospheric current connecting the field-aligned currents of Region 1 and Region 2 at the poleward and equatorward boundaries of the auroral ovals. As these currents are driven by the electric field produced by charge accumulation in the magnetosphere, they flow in the same direction as the electric field. The electrojet currents are thus at right angles to the electric field. Such a current, called a Hall current (after the Hall effect), is always present when an electric field is applied to a conductor containing a magnetic field.

Hall current

In the Earth's ionosphere the electrical conductivity parallel to the electric field is referred to as the Pedersen conductivity, and it is usually a factor of two less than the Hall conductivity perpendicular to the electric field. Consequently, the electrojet currents are actually stronger than the north–south ionospheric currents connecting the Region 1 and Region 2 currents. Typical disturbances produced by the westward electrojet are 500–1,000 nanoteslas, whereas those produced by the eastward electrojet are about half as large.

SOURCES OF VARIATION IN THE STEADY MAGNETIC FIELD

Secular variation of the main field. The main magnetic field of the Earth, as observed at the surface, changes continuously with time. Changes of very short duration compared with geologic processes are called secular variation. Observations of declination made in London since 1540, for example, show that the direction of the field at that site has nearly completed a full cycle with a peak-to-peak amplitude of 30°. Other components of the field have been observed for a shorter length of time, but they also are exhibiting similar rapid change.

The characteristics of the secular variation are often represented by superimposing maps of the rate of change of a given field component on maps of the component itself. Such maps reveal that the world may be broken down into regions of continental scale in which a given component is either increasing or decreasing. Changes can be as large as 150 nanoteslas per year and persist for tens of years. If maps of secular variation from successively later times are examined, many features of the secular variation are found to be displaced westward with time.

Manifestations of secular variation

The dominant component of the internal field is that of a centred dipole. It is useful to determine whether this component changes in the same way as the remainder of the field. Because the field of a dipole is so simple, it is more convenient to represent its change by its strength and orientation rather than by maps. Secular variation of the

non-dipole components, however, are usually presented as maps. Such maps are similar to maps of secular variation of the entire field, indicating that most of the secular change is caused by the non-dipole components. On the average, the non-dipole components of the field appear to drift westward at an average rate of 0.18° per year. At this rate, drifting features circle the Earth in only 2,000 years. Not all of the non-dipole field exhibits drift. At least half of it appears fixed and variable only in intensity.

The dipole component also changes with time. Its strength decreases with time. Since 1850 it has decreased from about 8.5×10^{22} to 8.0×10^{22} amperes per square metre. If this trend continues, the dipole component will vanish in another 2,000 years. As will be discussed in the next section, the dipole component of the Earth's field appears to be in the process of reversing.

The best estimates of the orientation of the dipole component appear to change with time. The dominant change is a westward drift of the azimuth of the dipole but at a rate much slower (0.08° per year) than the non-dipole component. The polar angles also may be increasing but even more slowly.

The origin of the secular variation is not known. Investigators suspect that it is a secondary effect of the dynamo mechanism that generates the main field. The short time scale of the variation implies that the source is in the outer region of the liquid core. If the source were deeper, the variation would be so attenuated by the electrical conductivity of the core that it would be undetectable at the surface.

Westward drift of magnetic anomalies

The westward drift of magnetic anomalies evident in the secular variation should provide an important clue to the origin of the main field if only it can be interpreted. One model explains the drift by postulating that the outer portion of the liquid core is rotating slower than the more rigid mantle above. As a whole, the Earth rotates eastward. If features within the core rotate more slowly than surface features, they will appear to move backward relative to the general rotation—*i.e.*, westward. In this model the secular variation is caused by portions of eddies in the internal current system that rotate more slowly than the planet as a whole.

A more recent model for the westward drift posits that it is produced by hydromagnetic waves in the core (see below *Magnetohydrodynamic waves—magnetic pulsations*). In this model the core rotates at the same rate as the outer mantle, but a wave propagates slowly around the outer portion of the core. Because waves in a conducting fluid distort the magnetic field frozen within it, they produce changes that can be observed at the surface. Since the characteristics of waves depend on the medium through which they propagate, it may be possible to infer properties of the outer core from surface observations.

Reversals of the main field. The Earth's internal magnetic field has not always been oriented as it is today. The direction of the dipole component reverses, on an average, about every 300,000 to 1,000,000 years. This reversal is very sudden on a geologic time scale, apparently taking about 5,000 years. The time between reversals is highly variable, sometimes occurring in less than 40,000 years and at other times remaining steady for as long as 35,000,000 years. No regularities or periodicities have yet been discovered in the pattern of reversals. A long interval of one polarity may be followed by a short interval of opposite polarity.

Available data suggest that during a reversal the strength of the dipole component shrinks to zero while maintaining its orientation. It then grows again to its former strength but with opposite orientation. During the interval in which there is no dipole component, the non-dipole part of the field appears to persist.

During field reversals the outer portion of the Earth's magnetic field is greatly altered. The absence of a dipole component would mean that the solar wind would approach much closer to the Earth. Cosmic-ray particles that are normally deflected by the Earth's field or are trapped in its outer portions would reach the surface of the planet. These particles might cause genetic damage in plant or animal communities, leading to the disappearance of one species and the appearance of another. Attempts have been made to establish whether there is evidence for such changes at the time of field reversals. Thus far the results remain inconclusive.

Evidence for magnetic field reversals

Evidence for the occurrence of magnetic reversals is unquestionable, however. Magnetic surveys made by ship across spreading centres in the middle of the oceans provide the best evidence. These data show that strips of oppositely magnetized ocean floor appear symmetrically about such features as the Mid-Atlantic Ridge. The explanation for these strips is that molten basalt flows out of the ridge and spreads away in both directions. As the basalt cools, it captures the orientation of the prevailing magnetic field and carries it along on the spreading seafloor. Basalt emerging from the ridge and cooling at later times captures the subsequent field orientation. The seafloor thus acts like a magnetic tape, capturing the alternating sequence of field orientations.

It should be noted that more information than the sense of the dipole component is captured in cooling rocks. Rocks formed at the magnetic equator, for example, contain a horizontal magnetization. Similarly, rocks formed at higher magnetic latitudes contain a field pointing up or down at an inclination that depends on latitude. The declination of the magnetization further reveals the direction to the magnetic pole at the time of the magnetization. Together, these two angles can be used to infer the location of a virtual magnetic pole relative to the location of the sample.

Such a technique has been used to study the history of the Earth's field at various locations. When virtual poles are determined from progressively older rocks, it is found that the virtual poles appear to wander with time. For many years it was thought that this "polar wandering" was a characteristic of the Earth's magnetic field. Recent studies, however, prove instead that it is a result of continental drift. Magnetic poles have not moved significantly relative to the geographic poles, but rather the continents have. Thus, progressively older rocks have been formed when continents were at different locations than they are today (see also below *Evidence for polar wandering, continental drift, and seafloor spreading*).

Cause of the reversals

Reversals in the main field must be caused by the dynamo mechanism that gives rise to the field in the first place. The time scale for the reversal is so rapid that it clearly cannot be caused by geologic processes. Furthermore, reversals cannot be caused by simple decay and reappearance of a preexisting field. The electrical conductivity of the core is too high to allow the field to decay on such a short time scale. In some way, minor changes in the magnetic field configuration of the core must be amplified by thermal convection, causing the field to grow rapidly in the opposite direction. Models that simulate the main field have been shown to possess this property. The solutions to equations that describe the generation of the main field are unstable, and small changes can cause solutions of opposite sign to appear.

Variations in the ionospheric dynamo current. The ionospheric dynamo is produced by movement of charged particles of the ionosphere across the Earth's main field. This motion is driven by the tidal effects of the Sun and the Moon and by solar heating. The ionospheric dynamo is thus controlled by two parameters: the distribution of winds and the distribution of electrical conductivity in the ionosphere. These parameters are influenced by several factors, including the orbital parameters of the Earth, Moon, and Sun; the solar cycle; solar flares; and solar eclipses. Changes in the position of the Sun and the Moon relative to the Earth as a result of orbital motions cause variations in distance. This alters the strength of the tides and of solar heating, thereby changing ionospheric wind patterns. These changes are apparent as a seasonal modulation of the winds and hence of the strength of the current.

The second parameter that controls the dynamo current is the electrical conductivity of the ionosphere. Any process that alters ionospheric conductivity changes the current. On the dayside of the Earth, the dominant source of ionization is sunlight. The amount of ionization depends

on the angle at which sunlight enters the atmosphere. Vertical incidence produces more ionization per unit volume than slant entry. For a given hemisphere, normal incidence occurs in summer. Thus, this effect also causes a strong seasonal modulation of the dynamo current.

Impact of sunspots and other solar activity

The degree of atmospheric ionization also depends on the phase of the solar cycle. This 11-year cycle of sunspot activity produces variations in the amount of ultraviolet radiation emitted by the Sun. More sunspots lead to more ultraviolet radiation and increased ionospheric conductivity, hence stronger currents. On a shorter time scale solar flares emit X rays that penetrate deeper in the atmosphere, temporarily ionizing the D region. Dynamo currents are then produced in this layer by whatever winds are present there.

A solar eclipse produces the opposite effect on ionospheric conductivity. The shadow of the Moon as it crosses the ionosphere decreases ionization. Recombination of ionospheric electrons and ions in the absence of light quickly reduces the conductivity. Because the effect is localized and of short duration, its effect on the overall dynamo current is slight.

Magnetic storms—growth of the ring current. The ring current is produced by the drift around the Earth of charged particles of the outer Van Allen radiation belt. During quiet conditions the effect of this current at the Earth's surface is negligible (~20 nanoteslas). Once or twice a month there occurs a phenomenon known as a magnetic storm, during which the intensity of the ring current increases and produces disturbances that are typically on the order of 100 nanoteslas but that can be as large as 500 nanoteslas. A variety of phenomena that affect humans occurs during magnetic storms. A few of these include increased radiation doses for occupants of transpolar flights, distortion of compass readings in polar regions, disruption of shortwave radio communications, increased corrosion in long pipelines, failure of electrical transmission lines, anomalies in the operations of communications satellites, and potentially lethal doses of radiation for astronauts in interplanetary spacecraft. Efforts have been undertaken to mitigate such serious problems. In the United States, for example, the federal government operates a Space Disturbance Forecast Center in Boulder, Colo., which monitors the state of the Sun and solar wind and attempts to predict the occurrence of such "space weather."

Cause of magnetic storms

It is known that magnetic storms are produced by a change in the properties of the solar wind. Magnetically quiet times occur when the solar wind contains a magnetic field called the interplanetary magnetic field (IMF) that has the same direction as the Earth's field on the dayside. Magnetic disturbances occur when this field rotates toward an antiparallel orientation. Normally, the IMF lies in the ecliptic plane, which on the average is roughly parallel to the Earth's magnetic equator. Small departures from this average orientation are caused by rotation of the tilted dipole magnetic field once per day and by revolution of the Earth around the Sun once per year. Large departures are caused by changes in the direction of the IMF relative to the ecliptic. Such changes are produced by several phenomena that originate on the Sun.

The most spectacular event that may cause a magnetic storm is a solar flare, which is an explosion in the corona of the Sun that releases an enormous amount of energy in the form of outward-streaming particles. The bulk of these particles takes approximately two days to arrive at the Earth, where they begin to influence its magnetic field. During transit the solar flare particles catch up with slower particles emitted earlier. The subsequent interaction of the high- and low-speed solar wind components causes a high-pressure region to develop, and this region tilts the IMF out of the plane of the ecliptic. If the IMF is tilted antiparallel to the Earth's field, a magnetic storm results.

Another phenomenon responsible for magnetic storms is the existence of coronal holes around the Sun. X-ray images of the Sun made during the 1970s by the U.S. Skylab astronauts revealed that the corona of the Sun is not homogeneous but often exhibits "holes"—regions within the solar atmosphere in which the density of gas is lower than in adjacent regions and from which charged particles escape with relative ease. Particles from such holes reach higher velocities in their outward expansion than do normal solar wind particles and produce high-speed streams. These streams interact with the slower speed solar wind emitted from regions without holes and produce the same tilting of the IMF described above. Coronal holes persist for many 27-day solar (equatorial) rotations and, as a consequence, produce recurrent magnetic storms. Coronal holes are the hypothetical m regions proposed many decades ago to explain recurrent storms that could not be associated with particular solar flares.

The observed dependence of geomagnetic activity on the orientation of the IMF is explained by most researchers as a consequence of magnetic reconnection. In reconnection, pictured schematically in Figure 22, two oppositely directed magnetic fields are brought together by flowing plasmas at an x-type neutral line. Far from the neutral line the magnetic field is frozen in the plasma; however, near the neutral line it becomes unfrozen and diffuses through the plasma, establishing a new configuration of magnetic field lines. On passing through the neutral line, field lines from opposite sides connect and flow rapidly away from the neutral line at right angles to their direction of inflow. In the process, energy originally stored in a strong magnetic field is converted to the kinetic energy of flowing plasma. In addition, the topology of magnetic field lines is changed. At the dayside magnetopause (see Figure 15),

Magnetic reconnection

From V.M. Vasyliunas, *Reviews of Geophysics and Space Physics*, vol. 13, p. 311 (1975), copyright by the American Geophysical Union

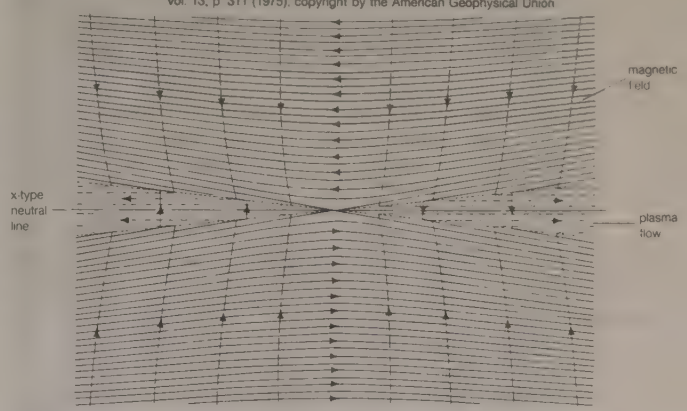

Figure 22: Magnetic reconnection at an x-type neutral line allows two plasmas threaded by magnetic fields to flow together and merge. (Plasma flow is represented by the dashed lines and the magnetic field lines by the solid lines.) A strong magnetic field in the inflow is converted to particle kinetic and thermal energy in the outflow region.

field lines of the IMF become connected to geomagnetic field lines. Because the IMF is frozen into the solar wind, the portion of the reconnected field line external to the magnetosphere is dragged away from the Sun above and below the polar caps. The portions of the field line inside must follow the external portions and, hence, their "feet" appear to drift across the polar caps. This process cannot go on indefinitely as geomagnetic field lines will be continuously eroded from the dayside unless they are replaced by an internal flow. Such a flow develops after a short lag and follows the same pattern as the return of field lines drawn away from the Sun by viscous interaction. When the flow is fully developed, the flux of magnetic field lines toward the Sun within the magnetosphere balances the flux away from the Sun above and below the polar caps.

For field lines to return from the nightside, they must first disconnect from the solar wind. This occurs at a second x-type neutral line located behind the Earth (see Figure 15). There, as on the dayside, oppositely directed field lines are brought together by plasma flows. Reconnection occurs, and the IMF and geomagnetic field lines again become separate entities.

The topology of magnetic field lines produced by the reconnection process accounts for the existence of auroral ovals. As evident from Figure 15, field lines of the polar caps are "open" to the solar wind, whereas those at lower latitudes are "closed." On the nightside the field lines con-

necting to the neutral line form a natural boundary for trapping charged particles. The region interior to the "last-closed field lines" is filled with trapped particles and is called the plasma sheet. The projection of the last-closed field lines on the polar atmosphere forms the poleward boundary of the nightside auroral oval. As previously noted, a second boundary forms on the nightside of the Earth as particles drift earthward under the influence of magnetospheric convection (driven by both viscous interaction and reconnection) and then enter the region of strong azimuthal drift. This boundary is called the inner edge of the plasma sheet, and it projects as the equatorward edge of the nightside auroral oval.

Generation of a magnetospheric electric field

An important consequence of reconnection is that it produces a magnetospheric electric field, as does viscous interaction. This comes about as a result of the connection between the interplanetary and geomagnetic fields. This process can be understood as follows. In the solar wind the Lorentz force separates positive and negative charges, just as it does in the magnetospheric boundary layer. These charges accumulate at boundaries within the solar wind where either the velocity or orientation of the IMF changes. There is an electric field between these boundaries. Because magnetic field lines have nearly infinite conductivity, the electric field originating in the solar wind is projected by magnetic field lines into the magnetosphere and onto the polar caps. The effect of this field depends on its strength and the length of the dayside x line. The voltage, or potential, drop caused by any electric field depends on the distance over which the field is applied. In dayside reconnection, not all interplanetary magnetic field lines connect to the Earth. Most slip around the magnetosphere. Consequently, the voltage applied to the polar cap is that which exists in the solar wind between the field lines that are reconnected at the ends of the x line. Usually this is 10–20 percent of the total voltage across a distance equal to the diameter of the magnetosphere. Even so, it can be as large as 200,000 volts.

A magnetic storm can be explained relatively simply in terms of the concept of magnetic reconnection described above. A solar flare or high-speed solar wind stream creates a high-pressure region in the solar wind. The leading edge of this region reaches the Earth and presses the magnetopause earthward. The sudden earthward motion and accompanying increase in strength of the magnetopause current cause an abrupt increase in the magnetic field at the Earth's surface known as the storm sudden commencement. In most cases, the pressure remains high for a number of hours and causes a larger than normal surface field. This interval is called the initial phase of a magnetic storm. Eventually, the IMF turns toward the south, antiparallel to the Earth's field, and magnetic reconnection begins. Closed magnetic field lines are eroded from the dayside and added to the polar caps, increasing their diameter. The aurora, which occurs in two ovals immediately equatorward of the polar caps, moves to lower latitudes. Within about an hour the nightside neutral line begins to return a sufficient amount of flux to the dayside, and convection approaches equilibrium.

Principal driving mechanism of magnetospheric convection

Magnetic reconnection drives magnetospheric convection much more efficiently than does viscous interaction. Consequently, all phenomena associated with convection are much enhanced over quiet times. Convecting particles approach closer to the Earth before they are deflected by drift in the main field. Field-aligned currents and the ionospheric electrojets driven by the convection electric field are much stronger. In addition, particles drifting across the main field gain more energy. This process of energization occurs at all times but is much enhanced during strong convection. It is caused by the dawn-to-dusk electric field across the magnetosphere. Any positive charge that drifts in the direction of an electric field gains energy from the field. Since positive charges on the nightside drift toward dusk, they gain energy. Similarly, electrons gain energy drifting toward dawn opposite to the electric field. On the dayside the drifts are reversed and particles lose energy. The combination of effects from more particles drifting faster closer to the Earth enhances the nightside ring current and reduces the magnetic field on the Earth's surface.

If the magnetospheric electric field remained steady, the particles drifting around the Earth would lose their energy on the dayside and convect to the magnetopause, where they would be lost to the solar wind. If the electric field across the magnetosphere is suddenly reduced by a northward turning of the IMF, however, many particles that would have been returned to the solar wind by convection are trapped on drift paths closed around the Earth. These particles rapidly separate into a doughnut-shaped ring that forms a symmetrical ring of current around the planet. Subsequent cycles of increase and decrease in the magnetospheric electric field trap additional particles and increase the energy of those already trapped. By this and another process described below, the ring current grows and produces the main phase of a magnetic storm.

A second and more spectacular phenomenon also contributes to the development of the storm main phase. This phenomenon is known as a magnetospheric substorm. The term substorm is used because such an event is observed during the development of the main phase of a storm. Since events of this kind occur more frequently at times when there is no significant growth of the ring current, they are treated below as a separate topic. As will be shown, the main effect of a substorm is energization and injection of particles into the inner magnetosphere in a localized region near midnight. Although the particles do not appear to have an immediate effect on the strength of the ring current, they are usually trapped on closed drift paths and are available for subsequent energization by fluctuations in the magnetospheric electric field. Many of the dramatic and often detrimental effects attributed to magnetic storms are actually caused by particularly intense substorms that accompany them. Both phenomena are linked by the same fundamental processes (see below).

Charge exchange and wave-particle interactions

The particles of the ring current have a finite lifetime before being lost to the Earth's atmosphere. Two processes—charge exchange and wave-particle interactions—contribute to this loss. Charge exchange is a process wherein a cold atmospheric neutral particle interacts with a positive ion of the ring current and exchanges an electron. The ion is converted to an energetic neutral, which, since it is no longer guided by the main field, may be lost in the deeper atmosphere, exchange again with an ion farther from the Earth, or be lost from the magnetosphere entirely. The previously neutral particle becomes charged in this process and is subsequently subject to drift in the main field, albeit with lower energy than the original ion. This process of charge exchange is dependent on the number of particles present in the ring current. As the number increases, so does the rate of decay due to charge exchange. For any given rate of injection into the ring current, the current grows until the rate of decay balances the rate of injection. At this point, the ring current becomes stable and persists as long as steady injection continues.

In a typical magnetic storm the interval during which the IMF is tilted out of the ecliptic antiparallel to the Earth's main field is on the order of eight to 16 hours. The lifetime of a particle against charge exchange is about the same. Accordingly, it is rare that equilibrium of the ring current ever develops. Instead, the IMF turns northward and the ring current gradually decays. In most cases, this recovery phase of the magnetic storm lasts for two to three days before quiet conditions are reestablished.

A second process that contributes to the decay of the ring current is the cyclotron instability of particles gyrating in the Earth's field. In this process an electromagnetic wave with a frequency near that at which particles gyrate about the field interacts with the particles exchanging energy. If conditions are right, the wave gains energy at the expense of the particle and in the process scatters the particle, so that it tends to follow a field line more closely. A succession of such scatterings eventually produces a particle moving directly along a magnetic field line. The particle then travels all the way to the atmosphere and is lost from the ring current. The appropriate condition for this process occurs when the ring current possesses more particles near the equatorial plane than near the end of the field line. Magnetospheric convection produces this situation in the inner magnetosphere; thus, this process is an

important loss mechanism contributing to the observed ring-current decay. In a typical ring current the waves produced by protons have a frequency between 0.2 and five hertz. Electrons produce waves of about 1,836 times higher frequency.

Magnetospheric substorms—unbalanced flux transfer. Magnetospheric substorm is the name applied to the collection of processes that occur throughout the magnetosphere at the time of an auroral and magnetic disturbance. The term substorm was originally used to signify that the processes produce an event, localized in time and space, which is distinct from a magnetic storm. During a typical three-hour substorm, the aurora near midnight exhibits a sequence of changes called the auroral substorm. Accompanying the changes in the aurora is a sequence of magnetic variations referred to as the polar magnetic substorm. Most of the detrimental effects of a magnetic storm are caused by the substorms that accompany them.

An isolated substorm begins when the IMF turns southward and dayside reconnection begins. For about an hour afterward, bands of quiet auroral arcs drift equatorward near midnight in the northern and southern auroral ovals. The eastward and westward electrojets, flowing from noon toward midnight along the ovals, gradually increase in strength and move equatorward along with the aurora. This quiescent phase is called the growth phase of the substorm.

Auroral breakup

The growth phase is terminated by a sudden brightening and activation of the most equatorward arc in each oval. This event is often termed the auroral breakup, and it signals the onset of the substorm expansion phase. Soon after onset, auroral activity expands to fill the entire sky above a particular ground observer. Rapid motion, development of vertical rays and folds, and the appearance of colour at the bottom of auroral forms are characteristic features of this phase. Detailed observations made from the ground and images from satellites reveal that the region of auroral disturbance expands poleward and westward. A surge of bright aurora, known as the westward traveling surge, propagates to the west and eventually decays into drifting bands that sometimes pass the dusk meridian. On the dawn side, patches of pulsating aurora and large omega-shaped bands drift eastward.

Accompanying the aurora are simultaneous changes in the magnetic disturbances. The most important of these is an enhancement of the westward electrojet in the region of the expanding aurora. As the surge travels westward, so too does the leading edge of the enhanced electrojet. On the ground the magnetic field suddenly decreases, sometimes by as much as 2,000 nanoteslas as the surge passes overhead. Behind the advancing fronts of the aurora, the particles responsible for the auroral light also increase the electrical conductivity of the ionosphere and cause the convection electrojets to increase in strength. The expansion phase of the substorm terminates after about 30 minutes, and the final phase begins.

The final phase of a substorm is called the recovery phase. During this phase the aurora and currents gradually drift back to their original equatorward locations as they simultaneously decrease in luminosity and strength. Provided that the IMF has turned northward in the intervening time, the recovery phase ends after approximately 90 minutes.

Often the IMF does not turn northward immediately; it may fluctuate between north and south. In such cases, the auroral and magnetic disturbances become much more complex and are not easily characterized. Situations of this kind usually persist for a sufficient length of time, so that many particles are brought into the inner magnetosphere where they are energized and trapped and produce a magnetic storm. Nonetheless, many features of the isolated substorm can still be recognized.

Substorms as manifestations of time-varying convection

The magnetospheric substorm also can be explained in terms of magnetic convection driven by magnetic reconnection. A substorm, however, is a manifestation of time-varying convection. In the reconnection model of substorms, transport of magnetic flux and particles never reaches equilibrium. During the growth phase of a substorm, magnetic flux is eroded from the dayside and added

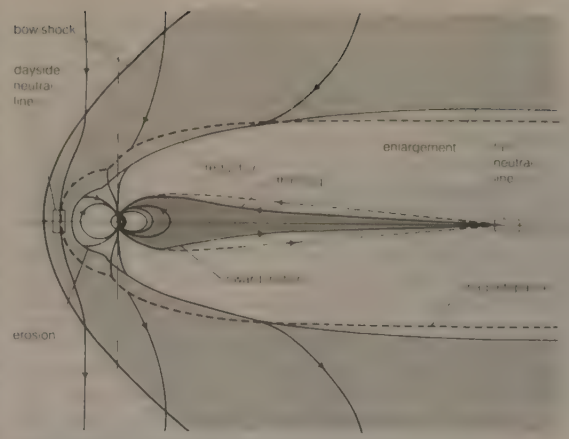

Figure 23: The growth phase is the name given to a sequence of changes in field configuration brought about by unbalanced flux transfer.

to the lobes of the magnetotail. As illustrated in Figure 23, the dayside magnetopause moves inward as a result of the flux lost, while the polar caps increase in size as a result of the flux gained. The additional flux in the near-tail requires an increase in the tail field and hence in the tail current, since the additional flux is contained in a volume of smaller cross section than was the initial quiet-time flux. Also, because the tangential drag on the tail has increased, the tail current moves earthward to increase the force that the Earth exerts on the tail, thus balancing the additional force of the solar wind. Closed flux simultaneously begins returning to the dayside and emptying the nightside plasma sheet. Equatorward motion of the aurora during this phase is simply a manifestation of the increasing size of the tail lobes. Enhancements of the eastward and westward electrojets are a consequence of the increased rate of convection driven by the southward IMF.

The expansion phase of a substorm

The expansion phase is less well understood than the growth phase. Many investigators support the "near-Earth neutral-line" model, but concurrently other explanations have been suggested. In the neutral-line model a localized x-type neutral line is formed inside the plasma sheet somewhere between 20 and 40 R_e (earth radii) behind the Earth. Figure 24 (top) shows the topology of the magnetic field when such a line is first formed. In the noon–midnight meridian of the magnetotail the magnetic field is divided into several regions by the simultaneous presence of two x-type neutral lines. Between the two x lines is an o-type neutral line around which there are closed loops of magnetic field. This field connects to neither the solar wind nor the Earth and remains in place only because it is surrounded by a sheath of field lines attached to the Earth. This geometry persists only as long as the sheath remains. Eventually reconnection severs the last-closed field lines, and subsequently open field lines of the tail lobe begin to reconnect. Shortly after this happens, the region of closed field lines is sheathed by field lines connected to the solar wind, as shown in Figure 24 (bottom). Tension in these field lines pulls the bubble of plasma and field, or plasmoid, as it is called, from the centre of the magnetotail. The plasmoid travels down the tail, collapsing the plasma sheet behind it.

In the neutral-line model, the sudden brightening of the auroral arc near midnight is thought to occur when reconnection reaches the last-closed field lines. The subsequent poleward expansion of the aurora is interpreted as the boundary of lobe field lines moving into the near-Earth neutral line to be reconnected. Finally, the westward surge is explained as an expansion of the azimuthal extent of the near-Earth neutral line by some as yet unexplained process.

In this model the final recovery stage of an isolated substorm is produced by a rapid tailward motion of the near-Earth neutral line. This probably occurs when there is no longer excess magnetic flux in the tail lobes to be returned to the dayside. Once this happens the magnetic field and plasma flow in the near-Earth region of the tail return

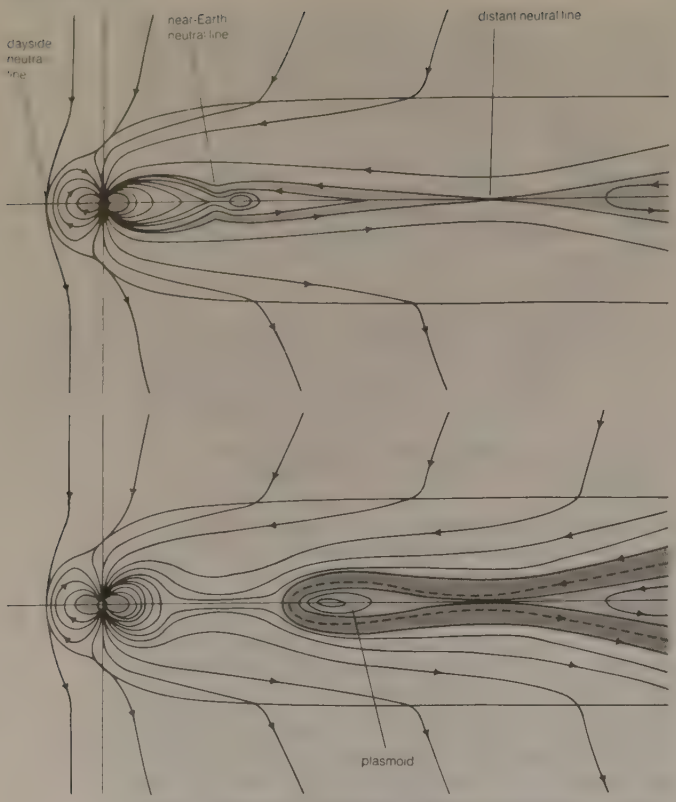

Figure 24: (Top) Magnetic reconnection inside the closed magnetic field lines of the plasma sheet, which produces a bubble of plasma and field called a plasmoid. The plasmoid is initially held in place by closed field lines attached to the Earth. (Bottom) When field lines in the boundary of the plasma sheet become reconnected, the plasmoid is pulled from the Earth's magnetotail by field lines connected to the solar wind.

to quiet-time conditions and reestablish the pre-substorm conditions of aurora and magnetic disturbance.

An essential feature of this model is that the near-Earth neutral line is azimuthally localized. To achieve this localization, it is necessary to divert a portion of the tail current to the ionosphere at the ends of the neutral line. The sense of this diversion is downward toward dawn and upward toward dusk, as shown schematically in Figure 25. In the ionosphere the current flows westward and enhances the preexisting westward convection electrojet. This current system is called the substorm wedge and, though not illustrated, connects symmetrically to both northern and southern auroral ovals.

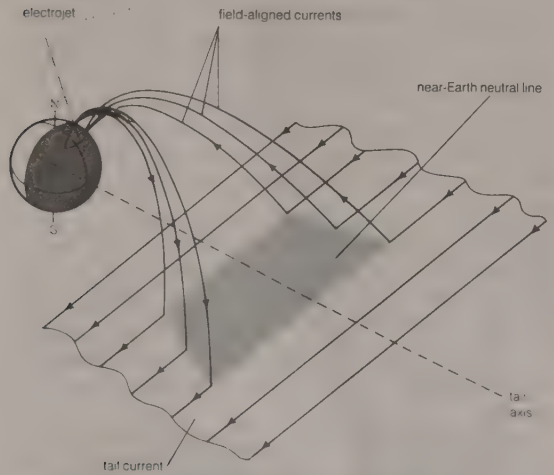

Figure 25: The substorm-wedge current is a field-aligned current system created when a localized x-type neutral line forms close to the Earth. A portion of the tail current is temporarily diverted through the ionosphere.

Substorm-wedge current system

The substorm-wedge current system causes sudden changes in the magnetic field at the Earth's surface during substorms. These changes induce very strong localized electric fields. These transient electric fields energize particles to high energy and propel them earthward. Loss of these particles to the atmosphere causes the aurora within the expanding bulge of the auroral substorm and later, as they drift, the ionization of the atmosphere that enhances electrical conductivity. Many particles also are trapped in drift paths around the Earth, adding to the particles in the ring current. On the ground, the same induction effects are responsible for the disruption of electrical transmission lines and for corrosion in pipelines. Changes in radio propagation are caused both by the changing size of the polar cap relative to lower latitude regions and by increased absorption of radio waves in the ionization occurring at the bottom of the ionosphere.

Magnetohydrodynamic waves—magnetic pulsations. A major source of variations in the Earth's magnetic field is magnetohydrodynamic waves. These waves originate in the outer magnetic field and propagate along field lines to the Earth's surface. On reaching the surface they cause minute oscillations in the magnetic field (hence their older name, micropulsations). These waves typically have amplitudes ranging from 100 to 0.1 nanoteslas, with lower frequencies exhibiting larger amplitudes. Magnetic pulsations have been classified phenomenologically on the basis of waveform into pulsations continuous (Pc) and pulsations irregular (Pi). Each class is subdivided into different frequency bands supposedly on the basis of boundaries defined by different generation mechanisms. By definition, magnetic pulsations fall into the class of electromagnetic waves called ultra low frequency (ULF) waves, with frequencies from one to 1,000 megahertz. Because the frequencies are so low, the waves are usually characterized by their period of oscillation (one to 1,000 seconds) rather than by frequency.

Magnetic pulsations

Until recently little was known about the causes of these waves. Improvements in instrumentation, notably DC amplifiers and spacecraft-borne devices, however, have contributed significantly to their understanding. There is a variety of mechanisms that produce such waves. The simplest mechanism is perhaps the resonant oscillation of the Earth's main magnetic field in response to waves in the solar wind. In this process a broad spectrum of waves of different frequencies is generated by some process in the solar wind. A small fraction of the energy in these waves penetrates the magnetopause. Within the magnetosphere each magnetic field line has a characteristic frequency of oscillation determined by its length, the strength of the field along it, and the mass of the particles attached to it. If the waves entering the magnetosphere have the same frequency as the field line, they force it to oscillate. If there is little damping of the oscillation, its amplitude may grow large enough to be observed at the ends of the field line. Additional sources of excitation include waves on the magnetopause stimulated by flow of the solar wind, sudden pressure pulses that move the magnetopause in or out, and sudden changes in the flow direction of the solar wind that cause the magnetotail to flap.

Generation of magnetohydrodynamic waves by cyclotron instability

Another type of generation mechanism is the cyclotron instability mentioned earlier in the discussion of ring-current decay. This mechanism illustrates the way in which a plasma may lower its total energy by creating waves. In this mechanism, a wave traveling along a field line interacts with a gyrating particle on the same field line. For energy to be exchanged, the electric field of the wave must rotate with the same frequency as that of the gyrating particle. If the particle has parallel as well as gyrational velocity, it is the wave frequency Doppler shifted to the frame of reference of the moving particle that is important.

Other instabilities are related to different periodicities in particle motion. Typical examples are bounce resonance of waves with particles traveling along field lines, or drift resonance with particles drifting around the Earth. In either case the electric field of the wave and the velocity of the particle must remain in phase with each other for a significant time so that energy is exchanged. (R.L.M.)

The structure and composition of the solid Earth

The basic structure and composition of the Earth's interior have been known since the mid-20th century. In a landmark paper published in 1952, the American geophysicist Francis Birch described the constitution of the planetary interior based on a broad array of seismological, experimental, and geochemical observations. Although there have been numerous advances in the intervening years, such developments have served largely to reinforce or extend the picture described by Birch. Thus, it is worth summarizing this basic picture before describing the detailed evidence on which current models of the Earth's interior are based.

Regions of the Earth

The Earth consists of two major regions: a central core, which is almost completely molten, surrounded by a predominantly solid shell comprising the mantle and crust together (Figure 26). The chemical compositions of these two regions are entirely different. The core is made of a dense, iron-rich metallic alloy, in contrast with the outer shell that consists of rocky (or ceramic-like) material. Oxides—specifically silicate minerals (compounds of silicon and oxygen)—make up this rocky material, with the crust containing somewhat more silicon, aluminum, and calcium relative to the mantle (Table 3). Examples of such minerals that are common in the outer few hundred kilometres of the planet (roughly down to 400 kilometres beneath the surface) include olivine, pyroxene, and garnet.

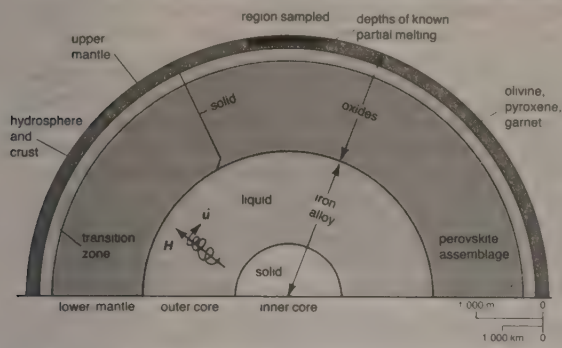

Figure 26: Schematic cross section illustrating the shell structure of the Earth.

Pressures and temperatures increase with depth inside the Earth, reaching maximum values of 364 gigapascals (GPa; 3,640,000 atmospheres) and about 6,000 kelvins (K; 10,300° Fahrenheit) at the centre. The interior temperatures are high enough to partially melt a small fraction of the crust and mantle and to completely melt the outer core. Most of the interior, however, including the inner core, is at a temperature below the melting point.

At depths of about 300 to 700 kilometres, pressures and temperatures become sufficiently high that the minerals of the upper mantle transform to more tightly packed crystal structures such as that of perovskite (see below). Because of the occurrence of these pressure-induced transformations, such physical properties as density and elastic-wave velocities are observed to increase rapidly with depth. This depth interval, called the transition zone, occurs about one-fifth of the way down into the mantle, separating the upper mantle from the lower mantle (Figure 26). Few, if any, significant mineral transformations seem to occur in the lower mantle, which is the single largest uniform region of the interior.

The fluid nature of the outer core has one consequence that can be felt directly at the surface. Turbulent flow of the liquid metal in the core effectively produces a dynamo. As noted above, the result is the main geomagnetic field (in Figure 26 the magnetic field and the fluid flow by which it is created are schematically indicated by $\boldsymbol{H}$ and $\vec{\boldsymbol{u}}$, respectively).

Although the mantle is solid in the conventional sense that its temperature is almost entirely below the melting point, this crystalline region is found to behave like a fluid over geologic time. Large-scale deformation of the mantle results in plate tectonics at the surface and the related phenomena of earthquakes and volcanoes.

This dynamic picture of the solid interior has been recognized since the 1960s, deriving largely from the realization that the crystalline solids making up the planet are ultimately weak. That is to say, laboratory experiments reveal that rocks can undergo substantial deformations over geologic time scales, particularly at the high temperatures of the interior. Also, innumerable geologic and geophysical observations at the Earth's surface are found to fit neatly into this picture of global tectonics involving large-scale deformations of the solid interior (see below *The surface of the Earth as a mosaic of plates*). Thus, it is concluded that the primary way by which heat is lost from the deep mantle and core is by convective flow, as though the mantle consisted of a highly viscous fluid. Viewing the planet as a large heat engine, one can see that it is convection that governs the thermal and chemical evolution of the Earth's interior.

ZONAL STRUCTURE AS REFLECTED BY VARIATIONS IN PHYSICAL PROPERTIES

Seismology: wave-velocity and density distributions. The main difficulty with studying the Earth's interior is apparent from Figure 26. Rock fragments (called xenoliths) are brought up volcanically from depth, thus providing samples of the upper mantle. These samples, however, seem to originate at depths no greater than 150 to 200 kilometres. Therefore, the material making up more than 90 percent of the interior is inaccessible to direct observation, and investigators must instead turn to indirect, geophysical approaches. Of these, seismology offers by far the most precise and detailed picture of the interior.

Seismic waves

Seismic waves are essentially elastic deformations that are generated by earthquakes, natural explosions (*e.g.*, volcanic eruptions), or artificial explosions (either nuclear or large chemical-explosive blasts). The waves propagate around or through the Earth, thereby revealing its internal structure.

Three types of seismic waves are commonly identified: body waves, free oscillations, and surface waves. Body waves are those passing through the interior, as illustrated in Figure 27. For large earthquakes, standing waves of the entire planet—free oscillations—are also excited. Intermediate between these types of seismic waves are surface waves, which travel around the surface of the globe. The definitions of these three wave types overlap: for example, free oscillations can be thought of as surface waves that are appropriately superposed to give a standing-wave pattern.

In general, seismic waves are similar to sound waves except that the periods of oscillation are far longer. Periods shorter than 0.1 second (frequencies of oscillation higher than 10 hertz), for example, are rarely considered in body-wave seismology, and this is at the lower limit of audible sound. Even though shorter-period (higher-frequency) waves are generated at the earthquake source, these are rapidly attenuated as they propagate through the Earth.

The longest period oscillations considered in seismology are those of free oscillations. These can range up to a period of 54 minutes (frequency of 0.3 millihertz). The limitation in this case is the size of the Earth: longer periods would require wavelengths longer than can be accommodated across the planet. The periods of surface waves are generally intermediate between those of body waves and free oscillations.

Two kinds of body waves are propagated through the solid parts of the Earth. They are longitudinal and transverse waves, which differ in the sense of deformation (or particle motion) associated with the wave. In geophysical literature they are commonly referred to as compressional (or *P*) and shear (or *S*) waves, respectively.

Compressional and shear waves

A compressional wave is in fact identical to a normal sound wave in that the deformation is in the same direction as that in which the wave is propagating. In contrast, the deformation in shear waves is perpendicular to the direction of propagation. As a result, shear waves can be transmitted only through solids. Because fluids have no rigidity (by definition), they cannot support the transverse deformation associated with shear waves.

Formally, the relationship between seismic-wave velocities and elastic properties is given by

$$V_P = \sqrt{\frac{K_S + \frac{4}{3}\mu}{\rho}}, \tag{27}$$

$$V_S = \sqrt{\frac{\mu}{\rho}}, \tag{28}$$

for compressional and shear waves, respectively. Both velocities depend on the rigidity (μ) and density (ρ), but V_P depends on the incompressibility (K_S) as well. Thus, in a fluid $\mu = 0$, $V_P = \sqrt{K_S/\rho}$, and $V_S = 0$. These relations, which are exact for a material that is isotropic in its elastic properties (K_S, μ), must be modified slightly in the case of anisotropy (*i.e.*, in case velocities or elastic properties vary with direction). For purposes of the present discussion, anisotropy can be ignored.

If the velocities inside the Earth were constant, seismic waves would travel in straight lines. Instead, the waves are reflected and refracted because of the variations in velocity, as is shown in Figure 27. These effects are completely analogous to the reflection and refraction of light waves caused by variations in refractive indices within a medium or between two mediums. (The index of refraction is simply the velocity of light in a material divided by the velocity in a vacuum.) In this sense, the body-wave seismologist treats the Earth as a large distorting lens and uses the distortions of the seismic ray paths to determine the variations of elastic-wave velocities throughout the interior.

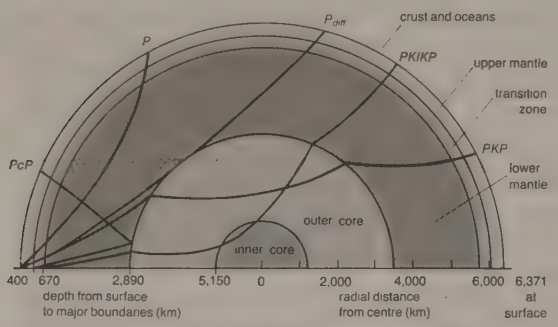

Figure 27: Cross section with shading proportional to the velocities of compressional (*P*) waves through the Earth. Several ray paths for compressional body waves are shown with labeling conventional in seismology: *P*, *K*, and *I* for compressional-wave paths outside the core, in the outer core, and in the inner core, respectively; *c* for a reflection from the core–mantle boundary; and subscript $_{diff}$ for a wave diffracted from the core–mantle boundary. Many more ray paths are observed, as are analogous paths for shear (*S*) waves.

Ray paths of body waves

A number of compressional-wave paths are illustrated in Figure 27. Many more paths have been observed, as have the analogous ray paths for shear waves. Classical seismology is based on measuring the time required for *P* and *S* waves to arrive at a seismic-wave recorder at the surface (seismometer) after following one of these paths from the earthquake source. For a given earthquake, several arrivals are usually observed at each seismometer; these correspond to waves arriving along different ray paths. Thus, based on studies of a large number of earthquakes, it is possible to infer the distribution of compressional- and shear-wave velocities throughout the Earth's interior.

Just such an analysis led to the travel-time tables and velocity-depth profiles published by Harold Jeffreys, the aforementioned British geophysicist, and Keith E. Bullen, a New Zealand seismologist, in the mid-1930s. Although there were several earlier and contemporary studies of travel times (by the American seismologists Beno Gutenberg and Charles F. Richter, for example), and numerous studies since then, the Jeffreys–Bullen model is considered to be an excellent first approximation for the compressional- and shear-wave velocity distributions with depth throughout the Earth.

In addition to the measurements of travel times, the determination of velocity distributions by body waves has been greatly enhanced since the late 1960s by the quantitative study of waveforms—the actual ground displacements as a function of time at each seismometer. The detailed character of these displacements, which might typically amount to a few to tens of micrometres (one micrometre equals 0.001 millimetre or roughly 0.000039 inch) for distant earthquakes, is extremely sensitive to the variation of velocity with depth. Therefore, if one starts with a reasonable estimate of the velocity-depth profiles (*e.g.*, based on travel times), these can be refined by calculating the waveforms from the velocity distributions and modifying these distributions in order to obtain the best match with the observed waveforms.

Study of waveforms

One of the problems with body-wave seismology is that only the V_P and V_S distributions can be determined; the individual variations of density and elastic moduli cannot be separated (equations 27 and 28). As a result, Francis Birch had to infer a density distribution for the interior in a roundabout way in his 1952 paper. First, any acceptable profile of density with depth must match the known density and moment of inertia for the Earth. Second, for a region of the interior that is uniform with depth (meaning that the mineral phases and overall composition remain constant), the change in density with depth must be related to the incompressibility, which is defined as the reciprocal of the relative change in density ($d\rho/\rho$) that is induced by a change in pressure (dP):

$$K_S = \left(\frac{dP}{d\rho/\rho}\right)_s. \tag{29}$$

As the ratio K_S/ρ (sometimes referred to as the seismic parameter, φ) can be derived from the measured values of V_P and V_S, this ratio can be used to constrain the variation of density with depth by way of equation 29. To do this, the increase in pressure with depth must be calculated as outlined below (equation 31).

Regions across which velocities vary smoothly, such as the lower mantle or the outer core, can plausibly be thought of as uniform with depth (see Figure 28). It is therefore reasonable to relate the density-depth profiles and the velocity distributions (specifically, $\varphi = V_P^2 - \frac{4}{3}V_S^2$) through these smooth regions. Once density is known with depth, profiles of the individual elastic moduli K_S and μ can be derived from V_P and V_S. This is an important accomplishment because density and elastic moduli vary in unrelated ways from one material to another or with changes in pressure and temperature; therefore, the velocities vary less systematically than either the moduli or density by themselves. It is the variation of these three properties, ρ, K_S, and μ, that are primarily used for inferring the nature of the Earth's interior.

The problem of deriving density profiles in this roundabout way from body-wave measurements was superseded

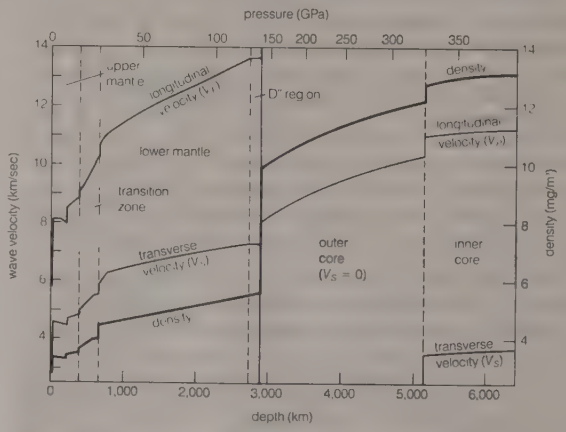

Figure 28: Summary of the average seismic-wave velocity and density profiles through the Earth according to the PREM model. The velocities of compressional (V_P) and shear (V_S) waves are given on the left, density on the right, and pressure as a function of depth on the top scale (see Table 2).

as of 1960. The first observations of free oscillations were made that year, and these allowed for determinations of the density variation throughout the interior.

Large earthquakes set the globe to vibrating in numerous modes of free oscillation. Dozens of these overtones have been recognized, and they can keep the Earth "ringing" for days after an earthquake. Two types of modes are observed: spheroidal and toroidal. These types involve motions toward (or away from) the centre of the globe and torsional motions of the globe, respectively. Evidently, these are roughly analogous to the compressional and shear waves of body-wave seismology, but they differ in that gravitational attraction as well as elasticity provide the restoring forces for the oscillations. The important consequence is that the periods of oscillation of the various modes are directly sensitive to the internal density distribution (see also EARTHQUAKES: *Long-period oscillations of the globe*).

Spheroidal and toroidal modes of free oscillations

There is no simple way to derive the velocity and density distributions directly from the observed periods of free oscillation. Instead, the theory of free oscillations only provides a means of calculating the periods of oscillation if the velocity and density distributions are known ahead of time. Moreover, it is necessary that the velocity distributions satisfy the observed body-wave travel times as well as the free-oscillation periods. Similarly, the density distribution must yield the known values of average density and moment of inertia for the planet.

Effectively what is done is to start with an initial estimate of the density and velocity distributions, calculate the observed properties (periods of oscillations, travel times, and so forth), compare these with the observations, and then refine the density and velocity distributions until the observed properties are satisfactorily reproduced. An elegant mathematical technique, pioneered by the American geophysicists George E. Backus and Freeman Gilbert, makes it possible to "invert" a large number of body-wave, surface-wave, and free-oscillation data in this manner so as to obtain density and velocity profiles that best reproduce the observations. The result is referred to as a seismological Earth model.

Constructing a seismological Earth model

As noted above, determinations of the density, V_P, and V_S profiles make it possible to derive the elastic moduli, K_S and μ, as functions of depth. In addition, the gravitational acceleration at each depth is given by the density profile:

$$g(r) = \frac{4\pi G}{r^2} \int_o^r r'^2 \rho(r')\, dr', \qquad (30)$$

where $G = 6.67259 \times 10^{-11}$ $m^3s^{-2}kg^{-1}$ is the gravitational constant and r is the distance from the Earth's centre (for depth z, $r = 6{,}371$ km $- z$ because the average radius of the planet is 6,371 kilometres). Using equation (30), it is possible to calculate the change in pressure (dP) with a change in depth (dz) according to

$$dP = \rho g dz. \qquad (31)$$

Clearly the pressure increases continuously with increasing depth (both ρ and g are positive), but, because ρ and g each depend on depth, the rate at which pressure increases varies with depth.

A technical point worth making is that equation (31) is valid only if the interior is hydrostatic (*i.e.*, shear stresses must be negligibly small, as in a fluid at rest). For this to hold, pressure must vary only with depth; pressure cannot vary laterally at a given depth. In fact, the interior is sufficiently hot that the rock is weak, and only small shear stresses can be sustained over geologic time periods. Maximum shear stresses in the mantle are estimated to be about 0.1 gigapascal, a value that is negligible in comparison with the pressures of the mantle and core. This justifies the use of equation (31) for determining the pressures within the Earth from the seismologically derived density profile. In a different context, however, the small deviations from hydrostaticity are extremely important, as it is exactly these deviations (or the corresponding shear stresses) that drive convection in the mantle and tectonic motions at the surface.

The first attempts to derive a standard Earth model that would be internationally agreed upon were made in the 1970s. The Preliminary Reference Earth Model (PREM) that emerged was presented in 1981 by the American geophysicists Adam M. Dziewonski and Don L. Anderson. This model is based on thousands of observations: travel times for body waves and periods for free oscillations. In addition, the variation of surface-wave velocities with frequency (or period) is used to constrain the V_P and V_S profiles, especially in the top 300 or so kilometres of the mantle. As the velocities and densities are assumed to vary only with radial distance from the Earth's centre (or equivalently, with depth from the surface) in deriving the Earth model, PREM yields laterally averaged values of properties. The resulting profiles of density and velocities are shown in Figure 28, and Table 2 summarizes a number of the seismologically determined properties as functions of depth.

PREM

The Earth's layered or shell structure, illustrated in Figure 26, is clearly defined by the seismic-wave velocities and density. The dominant boundary of the interior, that between the mantle and core, involves a nearly twofold increase in density, with a sharp drop in wave velocities (V_S going to zero) because of the lack of rigidity in the outer core. Next in order of magnitude are the crust–mantle boundary, the inner core–outer core boundary, and the mid-mantle discontinuities at 670 and 400 kilometres depth.

The lateral averaging of properties is more problematic at shallower depths, particularly for the crust and upper mantle, than deeper in the Earth. First, the distinction between oceans and continents (in roughly a proportion of 2 to 1 by area) is averaged out. Second, the variations in crustal thickness are also averaged. The crust–mantle boundary is conventionally taken at the Mohorovičić discontinuity, where the compressional-wave velocity increases sharply to values of eight kilometres per second or higher. The depth to the Mohorovičić discontinuity (*i.e.*, the thickness of the crust) is systematically greater under the continents than under the oceans: on average 35 kilometres and 6–7 kilometres, respectively. In fact, the crust can be as thick as 50–70 kilometres in some continental locations, while being less than a few kilometres thick in others (for example, the Himalayas as compared with parts of northeast Africa).

Thickness of the Earth's crust

The techniques of deep seismic sounding, carried out mainly in the United States and western Europe, have yielded high-resolution velocity profiles for the crust and uppermost mantle since the late 1960s. These studies, complemented by detailed waveform analyses and seismic tomography, prove conclusively that the crust and upper mantle can vary significantly in properties over horizontal distances of tens to hundreds of kilometres. Typically, the lateral variations in velocity are correlated with the tectonic activity that is observed at the surface; for example, young ocean basins (less than 20,000,000 years old), old ocean basins (more than 60,000,000 years old), cratons (continental crust older than 1,000,000,000 to 2,000,000,000 years in age), and tectonically active continental regions commonly exhibit different velocity profiles to depths of 200 kilometres or more.

Among the most notable examples of laterally variable structure is the presence of a low-velocity zone that is typically observed between about 60 and 150 kilometres beneath tectonically active regions, such as the western United States. Here V_P and V_S actually decrease over a limited depth range before resuming their usual increase with depth. The relatively high-velocity mantle overlying the low-velocity zone (wherever present) is referred to as the "lid." The lithosphere, which comprises the tectonic plates at the surface, is sometimes associated with the high-velocity crust and lid.

The sharp discontinuities in the seismic-wave velocities at depths of 400 and 670 kilometres separate the upper and lower mantle. The transition zone between the two discontinuities is a region of anomalously rapid increase in wave velocities with depth, as compared with the rest of the mantle.

Except for its top 100 kilometres and bottom 150–200 kilometres, the lower mantle is notable for its smooth,

continuous increase in velocities with depth. This is in contrast with the much larger velocity variations observed with depth in the overlying upper mantle and transition zone. Also, lateral variations in velocity averaged over 1,000-kilometre distances drop from about 4 to 8 percent in the upper mantle to about 1 to 2 percent in the lower mantle. These observations suggest that the lower mantle is a homogeneous region consisting essentially of a single rock type, whereas the upper mantle is not so uniform in bulk composition or mineral content.

Studies by Bullen and Birch in the 1940s and 1950s yielded a quantitative index of the homogeneity of a region. The local increase in density with increasing pressure is given by the incompressibility, K_S, which can be derived from the measured wave velocities (see equations 27, 28, and 29). As noted above, this was the basis prior to the study of free oscillations for calculating the density profile through regions that are assumed to be uniform in composition. With the free-oscillation measurements, however, the density profile with depth is obtained independently from the wave velocities. Expressing this density variation as a function of pressure rather than depth (see equations 30 and 31), an effective incompressibility can be defined by the relative change in density actually observed inside the Earth with changing pressure:

$$K_E = \frac{dP}{d\rho/\rho}. \tag{32}$$

The inhomogeneity parameter is then defined as the ratio of the density change predicted from the wave velocities to that actually observed from the free oscillations:

$$\eta = \frac{K_S}{K_E} = \frac{\varphi}{\rho g}\left(\frac{d\rho}{dz}\right). \tag{33}$$

For a homogeneous region, η is equal to one. If, however, composition or mineral phases vary with depth, then the density variation is not just determined by elastic compression and η is no longer close to one. Good examples of inhomogeneous regions include the upper mantle and transition zone (Table 2). In contrast, the lower mantle appears to be homogeneous in accord with the inference based on the small lateral variations in wave velocities throughout most of this region.

The D″ layer

The bottom 150 to 200 kilometres of the mantle, called the D″ layer, is highly anomalous relative to the rest of the lower mantle. There the average wave velocities appear to change little with depth (Figure 28). Also, detailed regional studies show that the velocity structure within D″ can be locally complex, with high- and low-velocity zones being present. In addition to the lateral heterogeneity that this implies, evidence that seismic waves can be strongly scattered in the D″ region suggests that large variations in velocity can occur over short distances. Possible explanations of these anomalies include the core–mantle boundary being corrugated with a few kilometres' "topography" (rather than being smooth), and the D″ layer being a region of chemical reaction or physical intermixing between the core and mantle.

Table 2: Structure and Properties of the Earth's Interior

region	depth (z, km)	pressure (P, GPa)	density (ρ, Mg/m³)	gravity acceleration (g, m/s²)	incompressibility (K_S, GPa)	rigidity* (μ, GPa)	quality factor* (Q, in shear)	inhomogeneity parameter (η)

*Values at a reference frequency of one hertz (one second period of oscillation) according to the Preliminary Reference Earth Model.
†Mass fraction of Earth.

Characteristics and structure of the Earth's core

Like most of the lower mantle (excluding the D″ layer), the core appears to be a relatively uniform region. It is perhaps for this reason, as well as the large contrast in properties across the core–mantle boundary, that the structure of the core had already been well determined by the 1940s. The presence of the core was inferred by the British scientist R.D. Oldham in 1906, and the depth to the core–mantle boundary (2,900 kilometres) was determined by 1914 through Gutenberg's work. In 1936 the Danish seismologist Inge Lehmann showed that the compressional-wave velocity increases deep inside the core, thus documenting the boundary between the central inner core and the surrounding outer core. Around 1970 the analysis of free oscillations provided independent and definitive confirmation for the presence and finite rigidity of the inner core, surrounded by a fluid outer core. In addition, the density profile derived from the free-oscillation data yields $\eta = 1$ for most of the core (Table 2). The homogeneity that this implies for the outer core is consistent with what would be expected for a fluid region that is being vigorously mixed by convection.

Electrical conductivity. The electrical conductivity at the Earth's surface is extremely variable and is largely dominated by the presence of water. Laboratory measurements, for example, show that the conductivity of seawater is close to four siemens per metre (S/m; or a resistivity of 0.23 ohm-metre), whereas dry rock exhibits conductivities in the range 10^{-11} to 10^{-9} siemens per metre. When water is present in rock, especially in interconnected pore spaces between the grains, the conductivity can range between 10^{-4} and one siemens per metre: approximately a billionfold enhancement over dry rock. Consequently, even though rock itself is electrically insulating, the conductivity of the crust is dependent on the occurrence of water within the rock matrix. In addition, high values of 10^5 siemens per metre or more can be found very locally because of the presence of metallic ores at the surface. Thus, averaging over this enormous spread of values, the near-surface conductivity of the Earth is in the range of 0.1 to one siemens per metre.

Mantle rock has a finite conductivity because many of the constituent minerals are semiconducting (*i.e.*, their conductivity is intermediate between values typical of insulators and metals, and it increases rapidly with increasing temperature). Water is thought to play a much less important role in the mantle because little is present, as compared with the crust. If temperatures become high enough to partially melt the rock, however, the melt can play the same role as water does at shallower depths in enhancing the conductivity. Therefore, mantle conductivity is expected to be sensitively dependent on temperature at depth.

The effect of temperature on mantle conductivity

The electrical conductivity of the mantle cannot be obtained by direct observation. Rather, it is derived by an indirect technique that is based on analyzing temporal variations in the Earth's magnetic field. Specifically, a mathematical description of the geomagnetic field, termed a spherical-harmonic expansion, makes it possible to separately identify that part of the field produced inside the Earth from the part produced externally. In 1838 the German mathematician Carl Friedrich Gauss used this approach to show that more than 95 percent of the field observed at the surface is internally produced. The approach, then, is to analyze the fluctuations of the internal field with time.

Because of the finite conductivity of the mantle, fluctuations in the external magnetic field induce electrical currents in the mantle in accordance with Maxwell's laws of electromagnetism. The electric currents, which are dependent on the conductivity of the mantle, in turn create a fluctuating magnetic field that is now of internal origin. Thus, the value of electrical conductivity in the mantle is derived by comparing the timing of external magnetic-field fluctuations with the induced internal-field fluctuations. In general, fluctuations of longer period are sensitive to conductivity at greater depths.

With this technique, the conductivity of the uppermost mantle has been found to be near 10^{-3} siemens per metre. Beneath continents the conductivity is roughly constant throughout the upper mantle, but beneath young ocean basins there appears to be a region of high conductivity (about 0.1 siemens per metre) between depths of 100 and 200 kilometres. Through the transition zone and the top of the lower mantle the conductivity increases, reaching values of one siemens per metre or more at a depth of 1,000 kilometres. Beyond this depth, conductivity values are not resolved because it is no longer possible to uniquely identify the long-period fluctuations of the internal field due to externally induced currents.

A similar approach can be applied to the lowermost mantle because the internal field generated in the core also fluctuates with time. Depending on the conductivity of the mantle, these fluctuations can be transmitted to the surface: the smaller the conductivity near the bottom of the mantle, the shorter are the periods of fluctuations that can reach the surface. Thus, the observation that internal magnetic-field fluctuations originating from the core seem to occur over periods longer than 3½ to four years can be used to constrain the conductivity to be in the range of 100 to 1,000 siemens per metre in the lowermost mantle.

High conductivity of the core

No direct measurements exist for the conductivity of the core, but this region must necessarily be highly conducting (metallic) in order to produce the geomagnetic field by a dynamo process (see above *The geomagnetic dynamo*). As will be discussed later, the core is thought to consist of an iron-rich alloy. The electrical conductivities of a number of plausible alloy compositions (*e.g.*, iron-sulfur, iron-silicon, and iron-oxygen compounds) have been experimentally measured at the pressures and temperatures existing in the core. The results uniformly point to a value about 10^6 to 10^7 siemens per metre being appropriate for the conductivity of the outer core. A summary of the estimated profile of electrical conductivity through the crust, mantle, and top of the core is included in Figure 29.

Temperature distribution. The temperature distribution through the Earth is mainly constrained by the seismological observations of which regions are solid and which are liquid—*i.e.*, which regions transmit shear waves and

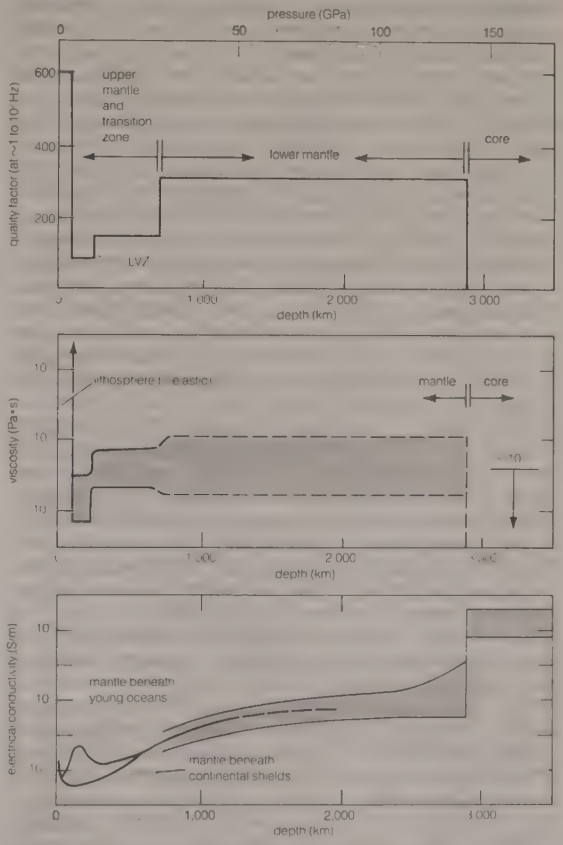

Figure 29: Profiles of the quality factor (Q; see Table 2), viscosity, and electrical conductivity as functions of depth. The quality factor is determined for shear waves at frequencies of one to 100 hertz (periods of one to 0.01 second).

which do not (Figures 26 and 28). Thus, the average temperature in the solid crust and mantle must be lower than the melting point of rocks that make up these regions. Similarly, the average temperature throughout the liquid outer core must be above the melting point of its constituent iron alloy. Presumably, the boundary between the solid inner core and liquid outer core is right at the melting temperature of this alloy.

As the core is considered to be made of nearly pure iron (see below *Zonal variations in chemical and mineralogical composition*), the temperature in the central portion of the Earth can be determined by studying the melting point of iron at high pressures. Even at the top of the core the conditions are fairly extreme, with pressures exceeding 130 gigapascals (Table 2). Nevertheless, two types of experiments have been carried out to determine melting points at these conditions: shock-wave experiments and diamond-cell experiments.

Shock-wave experiments

Shock-wave experiments involve hitting a rock sample with a projectile that is traveling at velocities of several kilometres per second. Upon impact, there is a brief period in which very high pressures and temperatures are achieved in the sample; typically, this lasts less than 0.000001 second before the sample is destroyed by the impact. In this brief period it is possible to measure the temperatures and pressures achieved, as well as the sound velocity through the sample. Thus when high enough temperatures are generated by this shock-compression to melt the sample, the sound velocity is seen to drop. This occurs because of the loss of rigidity on melting, and it is completely analogous to the drop in seismic-wave velocities observed from the inner core to the outer core (Figure 28).

Diamond-cell experiments

In diamond-cell experiments high pressures are achieved by pinching a sample between the points of two diamonds. Diamond is so strong (and hard) that pressures of several hundred gigapascals can be reached in this way. The advantage over shock-wave experiments is that the sample can be observed for hours or days at a time. The disadvantage, however, is that only small samples can be fitted between the diamond points: whereas grams of sample are used in shock-wave experiments, samples for the diamond cell are 1,000,000 times smaller. Temperatures and pressures are measured by direct observation of the sample through the transparent diamonds, and several techniques are available to achieve high temperatures. Perhaps the most notable involves heating the sample by means of a high-power laser beam focused through the diamonds.

With these two techniques, the melting point of iron has been determined to a pressure of 250 gigapascals. At this pressure, iron is found to melt at a temperature between 5,600 and 6,400 K. Because the outer core is known not to be pure iron, however, the effect of a small amount of contaminant on the melting point must be taken into account. This is difficult because of the uncertainty in the exact concentration of elements that might be alloyed into the core. Nevertheless, experiments carried out on a variety of iron alloys suggest that the melting point is lowered relative to that of pure iron, but by no more than 1,000 to 1,500 K. That is to say, the middle of the outer core must be above 4,000 to 5,500 K in order for this region to be molten (Figure 30). The entire inner core is then estimated to be at a temperature near 6,000 K once the increased pressure at this depth is taken into account. Similarly, considerations of the heat lost through the top of the core indicate that the temperature is lower in the outermost core—from about 3,700 to 5,000 K.

The melting temperatures of mantle minerals also have been experimentally determined under pressure. What has been found is that the melting point of mantle rock, about 1,500 K at zero pressure, rises rapidly with pressure but then becomes insensitive to pressure above approximately 20 gigapascals. Thus, the temperature of the lower mantle can be no more than 3,200 K for this region to be solid (Figure 30). Evidently the mantle is more than 1,000 K cooler than the core, which indicates that there must be a sharp increase in temperature near the core–mantle boundary.

Temperature difference between the mantle and core

Similarly, a rapid increase in temperature is known to occur through the crust and uppermost mantle. Very near

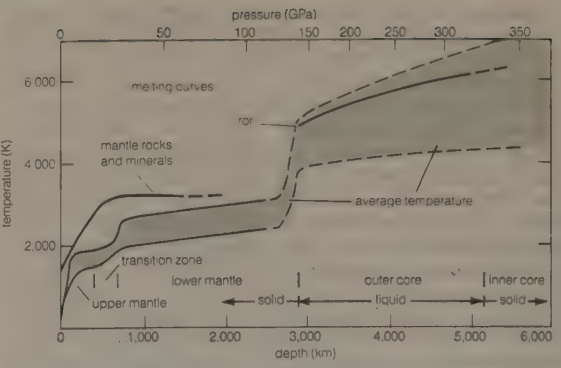

Figure 30: Estimated profile of average temperature at each depth, with the width of the shaded band illustrating the uncertainties. The curves in boldface show the melting temperatures that have been experimentally determined for minerals and rocks occurring in the mantle and for iron at high pressures.

the surface it is possible to directly measure the increase in temperature with depth; globally, the average increase is between about 10 and 30 K per kilometre (30 to 90° F per mile). Using this value and knowing from laboratory measurements that the thermal conductivity of rock is close to three watts per kelvin metre, the average rate of heat loss from the Earth's interior is calculated to be about 0.07 watt per square metre.

That the temperature in the deep crust and uppermost mantle is high is also documented by geologic observations. The detailed composition of the minerals making up a rock, for example, is usually sensitive to the temperature and pressure at which the rock formed. Rock fragments brought up volcanically from the upper mantle (xenoliths) typically contain olivine, pyroxene, and garnet minerals (see below). It has been found by laboratory experiments that if these minerals are heated together, the amount of calcium and magnesium contained in the pyroxene minerals varies systematically with temperature. In addition, increasing pressure results in increasing amounts of aluminum being present in the pyroxenes. Using these experimental results, the compositions of minerals in naturally occurring xenoliths can be interpreted in terms of their temperatures and pressures of formation. Recalling that pressure increases with increasing depth (see Table 2; Figure 28), one can find that temperatures between 1,000 and 1,800 K occur at depths of 100 to 250 kilometres.

The increase in temperature with depth is so rapid that if it continued unabated the melting curve of the mantle would be crossed by about 400 kilometres depth. Instead, as shown in Figure 30, the average temperature approaches the melting curve to about 150 kilometres beneath the surface and then changes little with depth. This sharp bend in the temperature profile is what keeps the mantle from being molten. Evidence for the bend comes from studies of mineral reactions at high pressures, which indicate that temperatures in the transition zone are roughly 1,500 to 2,000 K (see below).

The overall profile of average temperature with depth is characterized by "kinks"—regions of rapid increase with depth between which the temperature profile is relatively flat. The significance of these kinks became evident during the late 1960s when it was recognized that a vigorously convecting fluid has precisely such a temperature profile. As noted before, the mantle is solid but behaves like a fluid (*i.e.*, it convects vigorously) over geologic time periods.

In the interior of a fluid, corresponding to the interior of either the mantle or core, hot material rises and cold material sinks, thereby transporting (convecting) heat toward the surface very efficiently. Through this interior region of vertical motion, temperature changes little with depth. In contrast, fluid at the surface can move only horizontally; it is the near-surface horizontal movement of the mantle that produces plate tectonics (see below *The cause of plate motions*). In this region heat is transported horizontally, and the only way that the heat can escape outward is to be vertically conducted through the rock. As rocks

Heat flow in the mantle

are good thermal insulators, conduction is very inefficient (compared with convective transport of heat) and a large temperature gradient results with depth. One way to think of this is that though the surface of the Earth is cool, rock provides such good thermal insulation that the mantle close by can be very hot. This conductive region in which the temperature increases rapidly with depth is called a thermal boundary layer. Such a layer apparently occurs at the core–mantle boundary as well as at the surface.

Temperature variations near the Earth's surface

It is important to note that so far only the average temperature at a given depth has been considered. In fact, temperature varies considerably in the horizontal direction, as well as vertically, especially near the surface. Temperature differences as large as 1,200 K, for example, are present between volcanic areas in which lava (molten rock) is present and the rest of the crust. Globally, the most important volcanic structure is the mid-oceanic ridge system, at which new oceanic crust is produced. The rock underlying the oceanic ridges forms the hot, upwelling part of the mantle-convection pattern. In contrast, the lithosphere that sinks into the mantle at oceanic trenches (the subduction zones) forms the cold, downwelling part of the convection. This subducted lithosphere becomes warmed up as it sinks into the mantle. Thus, the variation in temperature at a given depth is greater than 1,000 K in the uppermost mantle, but it decreases with depth, becoming three or four times smaller in the lower mantle. In the core, horizontal temperature variations are expected to be 10 to 100 times smaller still, because the outer core is thought to have a low viscosity (*i.e.*, be extremely fluid).

Rheological properties. Rheology refers to the ease or difficulty with which a material deforms permanently rather than elastically. For a fluid this is characterized by viscosity, the ratio of the shear stress required to produce the deformation divided by the rate of the deformation. Solids can be characterized by a yield strength, given by the minimum stress required to produce permanent deformation (*e.g.*, fracturing). On geologic time scales, however, solid rocks at high temperature deform even under low shear stresses. Therefore, the rock can be thought of as having an effective (fluid-like) viscosity defined again as the ratio of the shear stress to the deformation rate.

Seismic anelasticity

Two effects by which the rheology of the interior is evaluated are seismic anelasticity and postglacial rebound. The first is based on the fact that minerals do not behave perfectly elastically in response to seismic waves but are slightly "mushy" under the deformations caused by the waves. As a result, seismic waves are attenuated, becoming smaller in amplitude as they travel through the interior. Similarly, free oscillations become damped with time. A quantitative measure of this anelasticity is the quality factor

$$Q = \frac{\pi}{\delta A/A}. \tag{34}$$

Here, $\delta A/A$ is the relative decrease in amplitude per oscillation of the seismic wave, and a high value of Q means that there is little attenuation. Also, the deformation energy that is lost to viscous damping is given by $2\pi/Q$ per cycle of oscillation.

Measurements of body-wave amplitudes as functions of distance of travel and observations of the decay rates of free-oscillation modes are used to derive a profile of Q with depth. The quality factor for shear deformation, which is inversely proportional to the amount of shear-wave attenuation, is shown in Figure 29 and included in Table 2. Most notable are the relatively high value near the surface (in the crust and mantle lid), the low value in the low-velocity zone, and the increasing values with further depth into the mantle. Shear Q is zero in the outer core, and it appears to be relatively small in the inner core (Table 2). By the definition of the quality factor, therefore, the most nearly elastic portion of the Earth is the high-Q zone near the surface.

Postglacial rebound

Postglacial rebound involves studying the deformation caused by Pleistocene (Ice Age) glaciers that covered much of North America and Scandinavia. The weight of the ice in these glaciers depressed the surface of the Earth by many hundreds to thousands of metres. As the load of ice has been removed by melting over the past 100,000 years, mantle rock is flowing back under the depression. Hence, the surface is moving upward and the depression is vanishing at a rate that is determined by how slowly the mantle flows—*i.e.*, how viscous the mantle is.

The rate of postglacial uplift is determined by measuring the ages of ancient beaches and the amount by which these beaches have been elevated above sea level. Typical rates are in the range of a few metres per 1,000 years. From such measurements at several locations, the viscosity profile through the upper mantle can be derived. What is found is that there is a low-viscosity layer underlying a surface layer that behaves elastically (Figure 29). The lithosphere is defined as being this top elastic layer, and it corresponds closely to the high-Q crust and lid that are observed seismologically. At depths beyond the transition zone, the viscosity profile is poorly resolved because motions due to postglacial uplift become vanishingly small.

As an illustration of how viscosity estimates can be used, consider the convective deformation of the mantle that is believed to cause plate tectonics. Taking plate velocities to be centimetres per year (10^{-2} metre in 3×10^7 seconds) and assuming that the deformation is across the approximately 3,000-kilometre thickness of the mantle, this yields a deformation rate of (10^{-2} m/3×10^7 s/3×10^6 m =) 10^{15} s^{-1}. Thus, with a mantle viscosity of about 10^{21} Pa · s (Figure 29), shear stresses of $10^{21}/10^{15} = 10^6$ Pa (pascals; or about 10 atmospheres) are sufficient to drive the observed tectonic motions. Compared with the mantle pressures listed in Table 2, the shear stresses are negligibly small. As previously indicated, the interior is almost perfectly hydrostatic, even though it is the deviations from hydrostaticity that cause tectonic motions.

The most interesting correlation among the profiles shown in Figures 28 and 29 is the occurrence of the low-Q, low-seismic-velocity, low-viscosity, and high-electrical-conductivity layers at about the same depth in the upper mantle. Apparently all of these measurements indicate that the rock is relatively soft or fluid at this depth. Referring to the temperature profile (Figure 30), this makes sense because it is precisely in this depth range that the rocks are brought most nearly to the melting point. Close to the melting temperature the rock would be expected to be softened and, especially if a small amount of partial melting occurs, the high electrical conductivity beneath young oceanic crust is similarly explained. Thus, there is a major rheological contrast between this layer, the so-called asthenosphere, and the relatively stiff lithosphere above it.

Presumed low viscosity of the core

The viscosity of the core is not well known but is thought to be low. By the mid-1980s, astronomical observations of the wobbling in the Earth's rotation could be interpreted to give an upper limit of about 10^3 pascal · seconds for the outer core. Measurements of the viscosity of molten iron extrapolated to high pressures, however, indicate that the outer core is likely to be at least 1,000 times less viscous.

ZONAL VARIATIONS IN CHEMICAL AND MINERALOGICAL COMPOSITION

Most of the Earth's surface is covered by oceanic crust. The composition of this crust is documented on the basis of rocks sampled by deep-sea dredging and by studies of ophiolites, which are slivers of oceanic crust and uppermost mantle that have been tectonically emplaced on land. The oceanic crust is found to be relatively uniform in composition (Table 3). It consists almost entirely of basalt (or the fully crystallized equivalent, gabbro), a rock containing pyroxene, plagioclase, olivine, and iron-oxide minerals, along with glass (see Table 4). The basalt is erupted at mid-oceanic ridges, solidifying to form new crust that is transported away from the ridge in the plate-tectonic cycle. In actuality, much of the oceanic basalt that is found has reacted with seawater after its formation and contains hydrous minerals such as serpentine ($[Mg,Fe]_3Si_2O_5[OH]_4$).

The continental crust is considerably more heterogeneous than oceanic crust and differs systematically from the latter in composition. Attempts to average the compositions of all continental rocks observed at the surface

Table 3: Estimates of Average Composition
(weight percent)

oceanic crust*		continental crust*		mantle*†		core

Difficulties in determining the average composition of the continental crust

or of sediments formed by erosion of large continental regions do not yield good estimates of the average crustal composition. This is because rocks formed in the deep continental crust are less often exposed at the surface than are those from shallower depths. Furthermore, the former appear to be systematically more depleted in silicon and enriched in calcium and aluminum than are the latter. Correcting for these differences leads to the estimate of average composition listed in Table 3. The composition of the continental crust corresponds roughly to that of andesite, which is considerably richer in silicon than the basalt constituting oceanic crust. Therefore, the deep continental crust is roughly intermediate in composition between the shallow continental crust and oceanic crust. Among the dominant minerals making up the continents are feldspars (mainly plagioclase), quartz, micas, and amphibole ($[Mg,Fe,Ca,Na]_{2-3}[Mg,Fe,Al]_5[Si,Al]_8O_{22}[OH]_2$).

The composition of the upper mantle is less easily determined than that of the crust. Samples of mantle rock come mainly from two sources: ophiolites and xenoliths. The latter, in particular, include rocks that have been brought from great depth by explosive eruptions. Most notably, the occurrence of diamonds with some xenoliths requires a source beyond 150 kilometres depth. As diamond is a high-pressure form of carbon, it converts rapidly to graphite when heated at a pressure less than five gigapascals, corresponding to this depth. Xenoliths range in composition from dunite, a rock made almost entirely of olivine, to eclogite. Eclogite is a variety of rock that is formed when basalt is taken to pressures exceeding 1.5 gigapascals; at such pressures the aluminum-bearing minerals, plagioclase and pyroxene in basalt, react to form new pyroxene and garnet in the eclogite. Common in xenoliths is peridotite, which consists mainly of olivine, pyroxene, and lesser amounts of plagioclase or garnet. As with basalt and eclogite, plagioclase is present if the peridotite is crystallized at low pressures and garnet is present if crystallized at higher pressures.

Peridotite as the dominant rock of the upper mantle

Based on the observed samples, peridotite with about 50 percent olivine, 30 percent pyroxene, and 15 percent garnet is considered to be the dominant rock of the upper mantle. This conclusion is supported by melting studies that demonstrate that a basaltic liquid is produced if peridotite is heated enough to melt partially. It is by partial melting of the upper mantle beneath mid-oceanic ridges that the basalt composing the oceanic crust is produced. The effect of this partial melting is to slightly deplete the original peridotite in aluminum and iron—elements that preferentially are concentrated into the basaltic liquid. Thus, the more aluminum- and iron-rich xenoliths are sometimes referred to as "fertile," meaning that they have not yet been significantly melted and could produce basaltic liquid upon partial melting.

Numerous experiments have been carried out at high pressures and temperatures to document the changes in mineral content and physical properties that occur in peridotite as it is taken to greater depths in the mantle. Among the most important changes are transformations of the minerals to denser crystal structures under pressure. In the 1960s and '70s, for example, studies by the Australian geochemist Alfred E. Ringwood and the Japanese geophysicist S.I. Akimoto showed that the pyroxene in peridotite transforms to the structure of garnet (the mineral is named majorite) and that the olivine transforms to phases with spinel-like crystalline structures (β-phase and γ-spinel, which have the mineral names wadsleyite and ringwoodite, respectively; see also MINERALS AND ROCKS: *Major rock-forming minerals: Olivines*).

The findings of Ringwood and Akimoto

One of the remarkable findings was that the transformation of olivine to its high-pressure (spinel) forms involves a jump in the elastic-wave velocities and density. Also, the transformation occurs suddenly at about the pressure of the 400-kilometre seismological discontinuity (Table 2). The boundary between the upper mantle and transition zone therefore takes on a natural explanation as being the depth at which the crystal structure of olivine that dominates the upper mantle transforms under pressure. Furthermore, the pressure at which this transformation occurs depends somewhat on temperature, an effect that has been experimentally calibrated. Thus, olivine transforms at exactly the pressure of the 400-kilometre discontinuity at a temperature of 1,700 K—a result that directly constrains the temperature in the transition zone, as noted above. In contrast with the olivine-spinel transition, the breakdown of pyroxene to form majorite occurs over an extended pressure range (rather than suddenly), and this can explain the anomalous increase in wave velocities through the transition zone (Figure 28).

In collaboration with Ringwood at the Australian National University, Lin-Gun Liu demonstrated in 1975 that

pyroxene further transforms to a dense phase with the perovskite structure. Liu, one of the pioneers in the application of the laser-heated diamond cell, subsequently showed that olivines, pyroxenes, and garnets of a wide variety of compositions all transform to the perovskite phase (sometimes with a coexisting oxide phase) at pressures above 15 to 25 gigapascals. This turned out to be especially significant when further research conducted in the United States showed that the perovskite phase of silicate minerals is stable to pressures existing at the core–mantle boundary. Apparently, peridotite of the upper mantle transforms almost entirely to the perovskite phase at the pressures near the top of the lower mantle, and the resulting perovskite exists throughout the deeper mantle. Because the lower mantle makes up more than 60 percent of the Earth on an atomic basis, silicate perovskite is considered to be by far the single most abundant mineral in the planet.

Silicate perovskite as the Earth's most abundant mineral

The crystal structure of perovskite is built up of SiO_6 octahedral units. In contrast, the minerals observed in the crust and upper mantle are characterized by SiO_4 tetrahedral building blocks. The tetrahedrons of the low-pressure structures are usually linked in complex arrangements, including chains and rings, to form the common minerals. At higher pressures, however, much denser packing of the atoms is achieved by locating six (rather than four) oxygen atoms around each silicon atom and by placing these octahedrons in a tightly packed arrangement. A good example is the mineral stishovite, which is the dense, high-pressure form of quartz (Table 4; stishovite was first synthesized in the laboratory by the Russian physicist Sergey M. Stishov and was subsequently discovered as a shock product in natural meteorite craters). In the mantle, silicon begins to form octahedral units in the garnet-structured majorite that occurs in the transition zone. The dominant change from tetrahedrally to octahedrally bonded silicon, however, occurs at the top of the lower mantle.

The changes in seismological properties with depth through the crust and mantle can be well understood either in terms of pressure-induced structural transformations, such as those just described, or in terms of relatively small changes in composition, such as the difference between the crust and mantle (see Table 3). In his studies of the Earth's interior, however, Birch already recognized that the change across the mantle–core boundary must be much more profound. Considering the seismological data alone, this boundary stands out as involving a large decrease in the seismic parameter, from $\varphi = 118$ km^2/sec^2 at the bottom of the mantle to $\varphi = 65$ km^2/sec^2 at the top of the core. These values are for adjoining regions across the boundary, which are therefore at the same temperature and pressure; also, because φ depends only on incompressibility and density, the lack of rigidity in the outer core does not come into play. For comparison, the seismic parameter changes by less than 15 km^2/sec^2 across the crust–mantle boundary and by only 2 to 4 km^2/sec^2 across the mid-mantle discontinuities and the inner core–outer core boundary.

The radical change in density from mantle to core is apparent in Figure 31. Also included are experimental measurements for a variety of compounds to show that the densities of magnesium, silicon, aluminum, and calcium oxides at elevated pressures and temperatures are in close agreement with the observed lower-mantle densities. This is in accord with the deep mantle consisting of high-pressure oxide or silicate minerals and contrasts sharply with the observed properties of the core.

Aside from having a high density, the generation of the magnetic field also requires that the core, unlike the mantle, be metallic. Birch's conclusion in 1952 was that iron is the most plausible constituent of the core. This was bolstered by subsequent work that has shown that iron is by far the most abundant element in the cosmos with density, elasticity, and electrical properties comparable to those of the core.

As seen in Figure 31, the outer core is about 10 percent less dense than iron at comparable pressures and temperatures. On this basis, the core is inferred to contain alloying elements or contaminants, such as sulfur or oxygen. The reasons for considering these particular elements

Alloying elements in the core

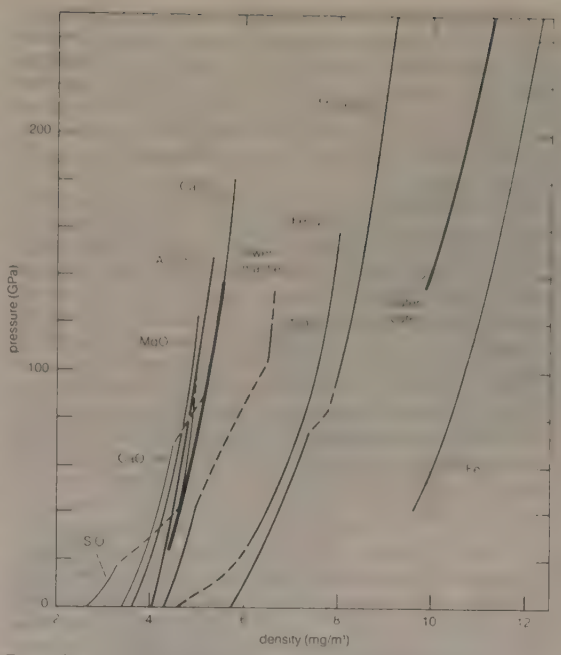

Figure 31: Summary of shock-wave data on the densities of oxides and iron compounds at high pressures and high temperatures. The seismologically derived pressure-density curves for the lower mantle and outer core are included for comparison.

as contaminants are somewhat tentative and are based largely on geochemical considerations, such as their cosmic abundances. Both iron oxide and sulfide are metallic at the conditions of the core, and both exhibit somewhat lower densities. By comparing densities of the iron compounds at elevated pressures and temperatures, it is found that the seismologically observed profiles of velocities and densities through the core can be matched by an alloy composition of about 90 percent iron by weight, with the remainder being sulfur, oxygen, and a variety of possible minor components (Table 3).

DEVELOPMENT OF THE EARTH'S STRUCTURE AND COMPOSITION

The origin of the Earth in its present form has been the subject of intellectual interest for centuries, but the decades since 1950 have seen major advances both in concepts and in measurements pertaining to this topic. The quantitative analysis by geochemists of the isotopes in meteorites and, in particular, the study of lunar rocks obtained during the U.S. Apollo program have produced some of the major contributions. In addition, geochemical research on terrestrial samples, combined with the new understanding of internal processes brought on by the recognition of plate tectonics, have significantly elucidated the ways in which the Earth has evolved.

The significance of nucleosynthesis

The astrophysical concept of nucleosynthesis remains the starting point in tracing planetary evolution. This includes the nuclear processes by which the light elements—hydrogen through boron—were produced at the birth of the universe, some 10,000,000,000 to 20,000,000,000 years ago. By analogy with what astronomers presently observe to happen, it is thought that the solar system represents preexisting cosmic gas and dust that was collected and compacted to extremely high density by a shock wave emanating from a nearby supernova (violently exploding star). Once sufficiently high pressures and densities were achieved, nucleosynthetic processes could begin within the solar mass to produce the elements that make up the solar system. The birth of the Sun, which makes up more than 99.9 percent of the mass of the entire solar system, is taken to be the time at which the planets started to form approximately 4,600,000,000 years ago.

As the vapour making up the solar nebula expanded and cooled, mineral grains are thought to have condensed and aggregated to form the earliest meteoritic material. In

addition, studies by the American geochemist Gerald J. Wasserburg suggest that material from outside the solar system, apparently existing prior to the formation of the Sun, was occasionally incorporated into meteorites. He has shown this by demonstrating that the concentrations of a variety of isotopes in a few meteorite fragments are highly anomalous, as seen in no other samples from inside the solar system.

Isotopic analyses

The concentrations of isotopes that decay radioactively and of isotopes that are produced by radioactive decay provide the information required to determine when meteorites and the planets formed. For example, the concentrations of rubidium-87 and the strontium-87 to which it decays, or those of samarium-147 and its decay product neodymium-143, indicate that the oldest meteorites formed 4,600,000,000 years ago. The American physicist John H. Reynolds further demonstrated that the Earth and meteorites formed at the same time—within at most a few tens of millions of years after the origin of the Sun. He did this by finding in meteorites anomalously high amounts of xenon-129 that could only have been produced in situ by the decay of iodine-129. Similarly, anomalous xenon-129 derived from iodine-129 is found to have escaped out of the Earth and into the atmosphere. Thus, iodine-129 must have been incorporated into both the Earth and meteorites when they were formed. As the half-life for radioactive decay of iodine-129 is 17,000,000 years, the Earth and meteorites could have formed no more than a few tens of millions of years after nucleosynthesis, when the Sun originated and iodine was formed. Later, essentially no iodine-129 was left to produce the anomalous xenon.

The most abundant elements in the Sun, hydrogen and helium, are severely depleted in the terrestrial planets of the inner solar system but are still abundant constituents of the large, gaseous planets of the outer solar system (*e.g.*, Jupiter and Saturn). It is thought that only in the colder regions of the outer solar system, including the zone beyond Pluto in which comets originated, could these volatile elements be retained during the formation of the planets. Considering only the less volatile (less gaseous) elements, however, it is found that the relative elemental abundances for the Sun, for a class of old and largely unaltered meteorites (called CI chondrites), and for the estimated composition of the Earth are all in close agreement. This

The chondritic model

is the basis for the chondritic model, which holds that the Earth was essentially composed of and has a composition similar to such meteorites. Isotopic analyses carried out in Wasserburg's laboratory during the late 1970s corroborate this idea: rocks derived from regions that are considered to be extremely primitive within the Earth (meaning that the regions have changed little through Earth history) exhibit concentrations of neodymium and samarium isotopes that are virtually identical to values obtained from chondritic meteorites. The reason that neodymium and samarium are considered is that these elements have similar volatilities and are both relatively involatile, making them good geochemical tracers. Thus, it appears that the composition of the Earth is roughly what would be expected given the observed abundances in the Sun, except that the lighter, more volatile elements were not retained very well as the planet formed.

The dust and grains that condensed out of the cooling solar gas aggregated to form larger fragments of rock. Chondritic meteorites are basically just such collections of grains and fragments that have been compacted together to form a larger piece of rock and eventually small planetary bodies. Such bodies are termed planetesimals when they become roughly as large as asteroids (several kilometres to a few hundred kilometres in dimension). The larger they grow, the greater the gravitational attraction that the planetesimals exert and hence the more effectively they sweep up additional particles and rock fragments while circling the Sun.

Both metallic meteorites (those composed largely of iron alloys of nickel and sulfur) and stone meteorites fall on the Earth today, and both types are thought to have been present during the accretion (or aggregation) of the planetesimals that were to form the Earth. That is to say, the Earth seems to have accreted after most, if not all, condensation of solids was complete. Thus, a wide range of minerals was included in the grains, larger fragments, and even planetesimals that were swept up by the growing planet. It seems that such an aggregation of dense metallic fragments and less dense rocky fragments is not very stable. Calculations based on the measured strengths of rocks indicate that the metallic fragments probably sank downward as the Earth grew. Although the planet was relatively cold at this stage (less than 500 K), the rock was weak. This is an important point because it leads to the conclusion that the Earth's core began to form during accretion of the planet and probably before the planet had grown to one-fifth of its final (present) volume.

Shock-heating of the Earth during accretion

During accretion the planet is thought to have been shock-heated by the impacts of meteoritic and planetesimal bodies. For meteorites this heating is concentrated near the surface (where the impacts occur), which is cooled by radiation back into space. The Russian planetary physicist V.S. Safronov has pointed out, however, that the larger planetesimals can penetrate sufficiently deeply upon impact to produce heating well beneath the surface. In addition, the debris formed on impact can blanket the planetary surface, which also helps to retain heat inside the planet. In this way, concludes Safronov, the Earth became hot enough to begin melting after growing to less than 15 percent of its final volume.

Among the planetesimals striking the Earth some 4,600,000,000 years ago, at least one is considered to have been comparable in size to the Earth—a large fraction of the present diameter of the planet. Although the details are not well understood, there is good evidence that the Moon was formed by the impact of such a large planetesimal on the Earth. Specifically, Ringwood has shown that the relative abundances of many trace elements in lunar rocks are close to the values obtained for the Earth's mantle. Unless this is a fortuitous coincidence, it points to the Moon having been derived from the mantle. Impact calculations suggest that a glancing collision of a large asteroid or small planetary body could have been sufficient to excavate the material that would form the Moon from out of the Earth's interior. Again, the evidence for such large collisions points to the Earth having been very effectively heated during accretion.

The conclusion is that many processes occurred almost simultaneously within a matter of tens to hundreds of million years after the Sun was formed. The evidence from xenon isotopes shows that meteorites and the Earth were formed within this time. Apparently the Moon, which is dated as more than 4,000,000,000 years old, was formed from the Earth's mantle in the same time period. Simultaneously, the core was accumulating toward the planetary centre, and may have been completely formed during the growth period of the Earth. In addition to the accretional heating caused by planetesimal impacts, the sinking of metal to form the core released large enough amounts of gravitational energy to heat the entire planet by 1,000 K or more. Thus, once core formation began, the Earth's interior became sufficiently hot to convect. Although it is not known whether or not plate tectonics was active at the surface, it seems quite possible that the underlying mantle convection began even before the planet had grown to its final dimensions.

Once hot, the Earth's interior could begin its chemical evolution. For example, outgassing of a fraction of those volatile elements that had been trapped (in small amounts) within the accreting planet probably formed the earliest atmosphere and oceans at this time. Also, chemical reactions between the mantle and core became possible in the deepest interior. From the perspective of surface geology, however, perhaps the most important event was the formation of crust by partial melting. This chemical separation by partial melting and devolatilization is termed differentiation.

Planetary differentiation

Exactly when and how the continental crust began to grow is uncertain, because the oldest rocks found so far are only 3,900,000,000 years old. These rocks were metamorphosed from preexisting crustal rocks, so it is known that the crust was present earlier in Earth history. In fact, one mineral grain, a zircon from Australia, has been dated

at 4,276,000,000 years in age, but its relation to the formation of continental crust is uncertain. Although direct evidence is not available, modeling of the isotopic compositions of rocks indicates that continental crust formed early. The analysis of neodymium and samarium isotopes and of rubidium and strontium isotopes, for example, suggests that the average age of continental crust is about 2,500,000,000 years. Thus, in all probability, repeated partial melting of the upper mantle formed successively more refined, continent-like crustal rocks starting from before 4,000,000,000 years ago. Over the first 1,000,000,000 years, however, much of the continental crust that was formed appears to have been reincorporated into the mantle: recycling rates of about one-third of the continental crust per 1,000,000,000 years are inferred from the isotopic data. As a result, only a few fragments of crust older than 3,500,000,000 years remain.

The process of partial melting and formation of crust, especially continental crust, leads to a depletion of certain elements (*e.g.*, silicon and aluminum) from the mantle. Relatively primitive and undepleted regions are still present, making up about one-third to one-half of the mantle, according to the isotopic models. The distribution of depleted and undepleted regions, however, is uncertain. Although much (perhaps all) of the upper mantle appears to be depleted, it is not known whether only the upper mantle is depleted or whether depleted rocks also occur in the lower mantle.

Continued chemical and thermal evolution of the Earth's interior

What is recognized is that the Earth is still differentiating, separating into chemically distinct layers or regions. This is most evident in the processes of plate tectonics that involve ongoing extraction of oceanic crust from the upper mantle. Although this crust is eventually subducted, along with overlying continent-derived sediments, remixing of oceanic or continental crustal material back into the mantle appears to be not very efficient. That is, the crustal material is physically returned to the mantle without being completely chemically homogenized. Thus, chemical and thermal evolution of the interior are intimately connected through convection, and the twofold process is still vigorously in progress some 4,600,000,000 years after the formation of the planet. (R.J.)

The major geologic features of the Earth's exterior

DEFORMATION OF THE CRUST

The Earth's crust has been subjected to widespread deformation over geologic time. This deformation results from forces applied to the rocks that make up the crust. Such forces create stresses within the rocks, and these stresses in turn produce strain, which is manifested in the form of folds, faults, and joints.

Force, stress, and strain. *Force.* This is a vector quantity that changes or tends to produce a change in the motion of a body. It is a push or pull and must be specified as to its direction and magnitude. If there is no acceleration of a body, the forces that act on it are balanced. There are four types: compression, tension (or extension), shear, and torsion. During compression, rocks are squeezed together by two equal forces acting toward each other along the same line. During tension, rocks are pulled apart by two forces acting away from each other along the same line. Shear is produced by a force couple; *i.e.*, rocks are subjected to two equal forces acting in opposite directions but not along the same line. Torsion is a twisting action produced by two opposed force couples acting in parallel planes.

Types of forces that deform rocks

Stress. When forces are applied to the external surface of a body, they set up internal stresses within it. Stress can be taken as a measure of the intensity of a force acting within the body. It is properly defined as the force per unit area within a body and is measured in dynes per square centimetre.

Strain. Any deformation caused by stress constitutes strain. It may be an increase or decrease in the length of an object, an alteration of its shape, or a change in its volume. It is generally measured as a percent elongation, percent shortening, angular distortion, or percent change in volume.

Geologic structures. *Folds.* Most folds are produced either by compression or by shearing of the Earth's crust. They generally occur in elongated belts and are produced within mountain systems. Folds in which rock layers are arched upward are called anticlines, and those in which the rock layers are bowed downward are called synclines (Figure 32). Homoclines are structures in which sedimentary rocks dip uniformly in one direction.

Parallel, similar, and flow folds

Folds can be classified on the basis of the form of the deformed rock layers. Parallel (concentric) folds are folds in which the layering in each bed is parallel to the layering in other beds and in which the layering forms concentric circles (Figure 32, left). Similar (slip) folds are those in which the layering in each bed is parallel to the layering in other beds and in which the form is the same in each layer in the fold (Figure 32, centre). Another type of major fold is the flow fold, in which the layering is neither parallel nor of the same form from one layer to another; instead, the layering is disharmonic (Figure 32, right). Flow folds form deep within the Earth's crust under conditions that produce metamorphism in the deformed rocks.

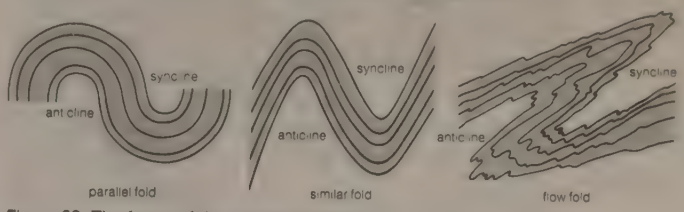

Figure 32: The forms of three types of folds.

Parallel folds usually develop as a result of compressional forces, such as those accompanying the collison of lithospheric plates. They tend to form at the outer margins of a fold belt. The so-called similar folds form due to shear stresses produced by a force couple in which both forces are oriented in a vertical plane. Shear folds often occur beneath major reverse faults or convergent plate margins. In such cases, the force couple that produces shear folds develops as a result of frictional resistance (drag) beneath the fault or plate margin. Flow folds can form either from compressive or shearing forces. As is the case in similar folds, both forces in the force couple that create flow folds are oriented in a vertical plane. Flow folds produced by compressional forces typically develop as a result of plate collisions, while those that form as a result of shearing forces develop beneath convergent plate margins. Flow folds form in the core of mountain belts and are exposed only after extensive erosion of the belts.

Faults. Faults are fractures along which movement has occurred. They are produced by compression, tension, or shearing of the Earth's crust. Faults can be characterized by the direction of movement along the fault plane. A dip-slip fault is a fracture in which the movement is parallel to the dip (direction of tilt) of the fault plane. A strike-slip is one in which the movement is parallel to the strike (direction or trend) of the fault. An oblique-slip fault shows a combination of both dip-slip and strike-slip movements.

Normal and reverse dip-slip faults

Dip-slip faults may be either normal or reverse, depending on the relative movement of the hanging wall and the footwall of the fault. (The hanging wall is the block lying above the fault surface, while the footwall is that which lies beneath the fault surface; see Figure 33.) In a normal fault the hanging wall is displaced downward relative to the footwall, whereas in a reverse fault the hanging wall is displaced upward. A structure bordered by two normal faults dipping toward each other is a graben.

Strike-slip faults may be either right-lateral or left-lateral. In a right-lateral strike-slip fault, the far side of the fault is displaced to the right. The opposite occurs in a left-lateral fault of this type. Most strike-slip faults form because of shearing of the Earth's crust. Such shearing occurs as a result of the development of a force couple in which both forces are oriented in the horizontal plane.

Some faults form as a result of gravitational rather than tectonic stresses. In Wyoming, for example, gravitational force caused large blocks of sedimentary and volcanic

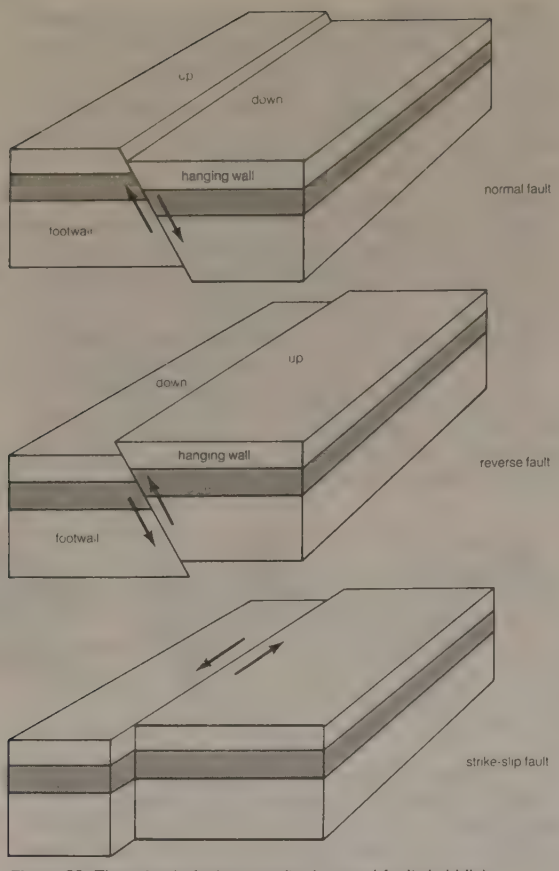

Figure 33: Three basic fault types: (top) normal fault, (middle) reverse fault, and (bottom) strike-slip fault.

rocks to slide tens of kilometres downhill along a fault surface called the Heart Mountain Detachment.

Joints. A joint is a fracture along which there has been no perceptible movement. Joints tend to occur in sets containing numerous subparallel joints, and typically there are two or three dominant joint sets in an area.

Joints have a variety of causes. They may be produced during the cooling of an igneous rock. Such joints are called primary joints, and all others are secondary joints. Cooling of an igneous rock results in its contraction, and this produces tension cracks. Features of this type are referred to as columnar joints if they tend to form long polygonal columns.

Sheeting

Joints also may be produced by the release of pressure on a massive igneous or sedimentary rock, such as granite or thick-bedded sandstone. Such jointing is termed sheeting. It occurs when a rock that has been deeply buried under hydrostatic pressure (pressure equal in all directions) is exposed relatively rapidly by erosion, resulting in a significant reduction in the pressure perpendicular to the erosion surface. Fracturing is caused by residual stresses oriented parallel to the erosion surface.

Another major cause of joints is regional stresses. Both compressive and shear stresses tend to produce joints along which there has been a slight but not perceptible movement. Such joints are called shear joints, and they are incipient faults. Regional tension would produce a vertical joint set oriented at right angles to the direction of extension. Regional torsion generates local tension that may give rise to intersecting joint sets. Experimentally produced torsion fractures closely resemble fractures found in sedimentary rocks in the mid-continental region of North America. Regional torsion may be produced by differential uplift of sedimentary sequences within the mid-continent where domes are uplifted more than the adjacent basins. It also may be caused by Earth tides generated as a result of the gravitational attraction between the solid Earth and both the Moon and Sun. Earth tides lift the outer surface of the planet about 20 centimetres. Such uplifts would cause repeated flexing of the Earth's crust and could induce jointing in sedimentary layers.

PHYSIOGRAPHIC EXPRESSIONS OF CRUSTAL DEFORMATION

Folding and faulting of the Earth's crust produces mountains, such as the Rocky Mountains, Appalachian Mountains, Himalayas, and Alps. Jointing, by contrast, plays only a minor role in shaping the terrestrial surface.

Folding. Compression of the Earth's surface results in the formation of mountain ranges in which rocks are extensively folded. Erosion of a sequence of sedimentary rocks containing beds, some of which are easily eroded and others of which are resistant to erosion, produces numerous parallel ridges and valleys that are oriented parallel to the mountain belt in which they are found. Such ridges and valleys are well developed in the Valley and Ridge Province in the Appalachians and in the eastern part of the northern Canadian Rockies. Ridges may be underlain by anticlines, synclines, or homoclines (Figure 34). Valleys also may be underlain by anticlines, synclines, and homoclinal ridges or homoclines (Figure 34). Anticlinal, synclinal, and homoclinal ridges have resistant sedimentary layers beneath them, whereas the corresponding types of valleys are underlain by less resistant layers.

Faulting. This type of fracturing results either from the compression or the extension of the Earth's crust, and it may lead to the formation either of parallel mountain ranges and valleys or of one or two very elongated valleys bordered by broad uplifts instead of mountain ranges.

Extension of the Earth's crust may result in the formation of numerous parallel ridges and valleys oriented perpendicular to the direction of extension. Such extension may occur parallel to the coastline of a continent and cause parallel sets of normal faults to form. Generally ridges develop along the uplifted block of the footwall of a normal fault, while valleys form along the dropped block of its hanging wall. The Basin and Range Province of the western United States is a region in which ridges have been uplifted and valleys have been dropped along normal faults. This region may have been subjected to extension as a result of the formation of a broad arch underlying the Basin and Range Province. Stretching of the Earth's crust at the top of the arch may have created the extension, which in turn produced the normal faulting.

Formation of long valleys underlain by grabens

Normal faults bordering grabens are formed by crustal extension, and this results in the formation of long valleys underlain by the hanging walls of the normal faults that have been dropped relative to the footwalls of the uplifted blocks bordering the valleys. The East African Rift System is an excellent example of a series of valleys underlain by grabens formed by crustal extension.

Reverse faults are common in mountain belts and are partly responsible for the formation of the belts. Ridges often occur along the uplifted hanging walls of low-angle

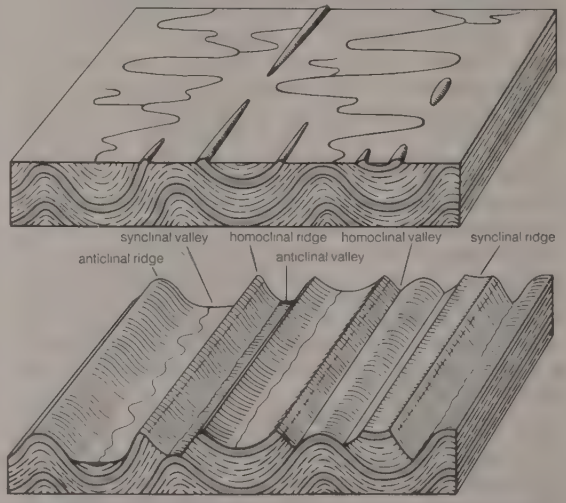

Figure 34: The topographic expressions of eroded anticlines and synclines.

reverse faults in mountains such as the northern Rockies in western Canada and the northwestern United States. Valleys develop between these uplifted blocks in part because the rocks along low-angle reverse faults are brecciated during faulting and are thus less resistant to erosion.

High-angle reverse faults border many of the mountain ranges of the central and southern Rockies. There, the uplifted hanging walls of the faults form large mountains that are somewhat isolated from one another and often are not parallel to each other. This contrasts with the mountains of the northern Rockies, which tend to parallel each other and are connected together. The mountains of the central and southern Rockies are separated by broad basins in which thick sequences of sedimentary rocks have been deposited as a result of erosion of the adjacent mountain ranges.

Many strike-slip faults contain a zone several kilometres wide along which rocks are intensely brecciated and sheared. Erosion of these brecciated and sheared zones commonly results in the formation of an elongated valley paralleling the underlying fault zone. Such valleys are common along the San Andreas Fault in California, particularly in the region south of San Francisco.

Formation of joints. Because joints are areas of weakness in sedimentary rocks, erosion may occur more readily along regions in which joints are closely spaced. Consequently, streams in some areas of jointed rocks tend to parallel one or more joint sets.

THE SURFACE OF THE EARTH AS A MOSAIC OF PLATES

When earthquake epicentres are plotted on a map of the world, it is apparent that most of them are confined to relatively narrow bands rather than being uniformly distributed over the Earth's surface. The narrow bands along which earthquakes occur are located at the margins of large plates that are moving relative to each other. As previously noted, these plates consist of the entire crust of the Earth plus a significant portion of the upper mantle. About a dozen plates make up the Earth's surface. (For a detailed discussion of this subject and a map of the principal plates, see the article PLATE TECTONICS.)

Size of the plates

Geometry and rates of plate movement. The plates range in size from about 400 by 2,500 kilometres to 10,000 by 10,000 kilometres. Some Earth scientists believe that the plates are equal in thickness to the lithosphere (see above). If this is so, the plates would be between 70 and 225 kilometres thick. Other investigators hold that the lithosphere moves along with the asthenosphere (the relatively plastic layer underlying the lithosphere) and perhaps the top of the mesosphere as well. In this case, the plates could be as much as 650 kilometres in thickness. Because earthquakes extend to depths of 650 to 700 kilometres, it is clear that plate movements extend to at least that depth.

There are two types of plates, continental and oceanic. An example of a continental plate is the North American Plate, which includes North America as well as the oceanic crust between it and a portion of the Mid-Atlantic Ridge. Oceanic plates are made up primarily of oceanic crust. A plate of this type is exemplified by the Pacific Plate, which extends from the East Pacific Rise to the trenches bordering the western part of the Pacific Basin.

The velocities of plates vary with distance from the spreading pole of the plates. The spreading pole is an imaginary axis about which one plate moves relative to another. At any one time, the velocity of plates will be at a maximum 90° (great circle degrees) away from the spreading pole and will be at a minimum at or near the pole of spreading. At present there are significant differences between the maximum spreading velocities of oceanic plates and those of continental plates. In general, the maximum velocity of spreading of the oceanic plates is two to four times that of the latter. The maximum spreading velocity of the Pacific Plate relative to the East Pacific Rise, for example, is about eight centimetres per year, while that of the North American Plate relative to the Mid-Atlantic Ridge is roughly two centimetres per year.

Types of plate boundaries. As explained earlier, there are three types of plate boundaries: divergent, convergent, and transform (or strike-slip). Plates move in opposite directions along the same line at divergent plate boundaries. These boundaries are located at mid-oceanic ridges (spreading ridges) such as the Mid-Atlantic Ridge and the East Pacific Rise. Ridges of this kind are part of a worldwide system of ridges that generally occur at the centres of ocean basins. The system forms an undersea mountain chain measuring more than 60,000 kilometres in length. Most or perhaps all of the component ridges originally formed beneath continents at the time when continental fragmentation began. Take for example the Mid-Atlantic Ridge, which emerged about 200,000,000 years ago when North America and Eurasia began to separate from Gondwanaland (which consisted roughly of present-day South America, Africa, India, Australia, and Antarctica).

Divergent plate boundaries

The second type of plate boundary, the convergent boundary, forms where two plates move toward each other along the same line. Such boundaries are located either at or near the margin of a continent where the seafloor moves under the continental margin along a subduction zone, or within a continent where two continents collide. Oceanic trenches typically occur along subduction zones. The trenches bordering the Pacific Basin (*e.g.*, the Peru-Chile Trench and the Aleutian Trench) are located along such convergent plate boundaries. Intracontinental mountain ranges occur along convergent plate boundaries where two continents are colliding. The Himalayas are situated along a plate boundary of this sort.

Convergent plate boundaries

The third type of plate boundary, the transform variety, forms where two plates are moving in opposite directions but not along the same line. Transform boundaries are located along transform faults, which are a type of strike-slip fault, as, for example, the San Andreas Fault. Such faults develop where the motion of plates is transformed from one type of motion to another. The most common type of transform fault offsets spreading ridges (Figure 35). Here, the motion is transformed from along the fault. The actual motion along such a transform fault is exactly the opposite of the apparent offset of the spreading ridge. Transform faults also may connect two trenches, a ridge and a trench, a mountain and a ridge, and so forth.

Transform plate boundaries

Activity along plate boundaries. In addition to earthquakes, most of the faulting, folding, igneous activity, metamorphism, and mountain building on the Earth occurs at or near plate boundaries.

Earthquakes. Most Earth scientists believe that virtually all naturally produced earthquakes occur as a result of movements along faults. The reason that the majority of such earthquakes occur along plate boundaries is that most faults lie along those boundaries.

Faulting. Normal faults are very common along divergent plate boundaries because these are regions of crustal stretching (tension). The oceanic crust along the crests of mid-oceanic ridges is cut by numerous normal faults trending parallel to the ridge crests (Figure 36). Most of

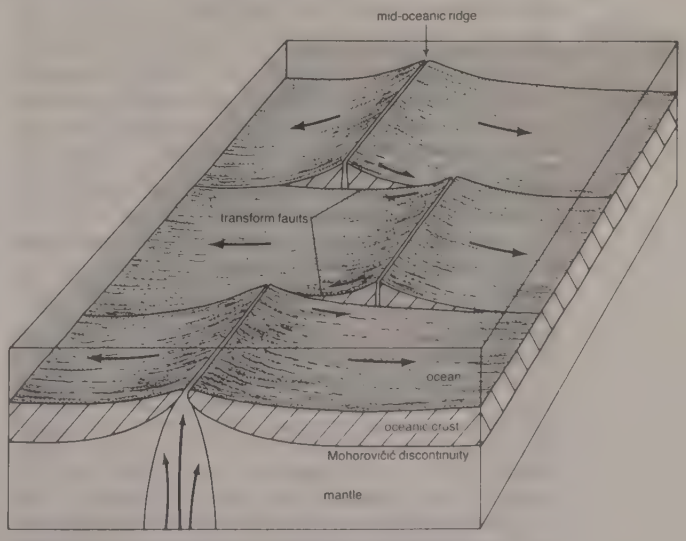

Figure 35: Two transform faults offsetting a mid-oceanic ridge.

these faults, however, are located below sea level and can be found only by submarine depth profiling.

Normal faults are formed in continental crust along divergent plate boundaries when two continents begin to separate from each other. Continental crust is uplifted, stretched, and faulted over the convection current that caused the continents to separate. Such faults formed along the margins of the Atlantic and Indian oceans when the continents began to pull apart from each other approximately 200,000,000 years ago. The majority of these faults are covered either by younger sedimentary deposits that now underlie the continental shelf or by deposits of the coastal plains bordering the oceans.

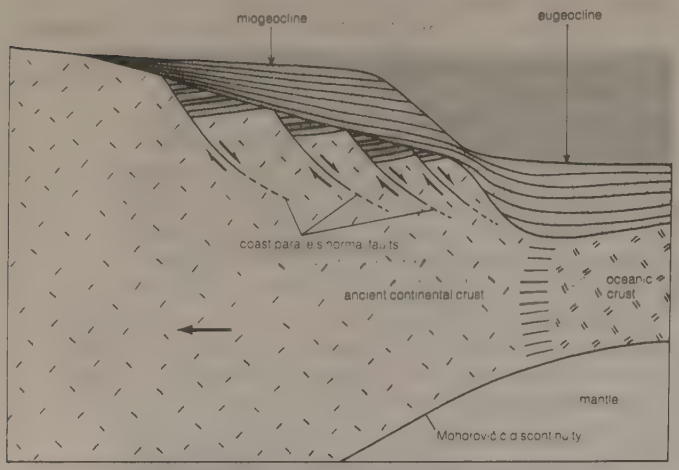

Figure 36: Cross section of a continental margin adjacent to a divergent plate boundary.

Reverse faults are very common along convergent plate boundaries where rocks are undergoing compression. They are found in areas where the seafloor is moving beneath continental margins along subduction zones and in areas where two continents collide. Reverse faults may be produced beneath a plate margin in a subduction zone (Figure 37, top). They also may develop above the plate margin along a wide belt on the continental margin parallel to the flanks of a mountain range (Figure 37, bottom). Reverse faults are common along the Pacific margin of continents. They also may be produced both in front of and beneath an overriding continent where two continents push together (Figure 38). Many are found in the Himalayas and the southern Appalachians. The Himalayas are at the present time the site of a collision between India and Asia, while the southern Appalachians were the site of a continent–continent collision some 250,000,000 to 350,000,000 years ago. Normal and strike-slip faults also occur along convergent plate boundaries, but they are less common than reverse faults in such areas.

Strike-slip faults

Strike-slip faults frequently occur along transform boundaries and, in fact, constitute such boundaries. Strike-slip faults, however, may also be formed as a result of stresses produced in the Earth's crust by movement along adjacent primary strike-slip faults. Such strike-slip faults are termed secondary faults and may develop as a result of drag produced by frictional resistance along the primary faults. Secondary normal and reverse faults also may be formed by drag along primary strike-slip faults.

Folding. Folds are produced principally at convergent plate boundaries, but minor secondary folds develop along transform plate boundaries due to drag. They are found along plate boundaries adjacent to subduction zones where oceanic plates are moving beneath continental plates and where one continent collides with another continent.

Folds along subduction zones are attributable to shear stresses created by drag resulting from frictional resistance between the two plates (Figure 37, top). They are associated spatially with the reverse faults in subduction zones discussed above. The sedimentary and volcanic rocks in the Klamath Mountains of northern California contain such folds and faults. Folds also are produced above subduction zones as a result of the compression of plate

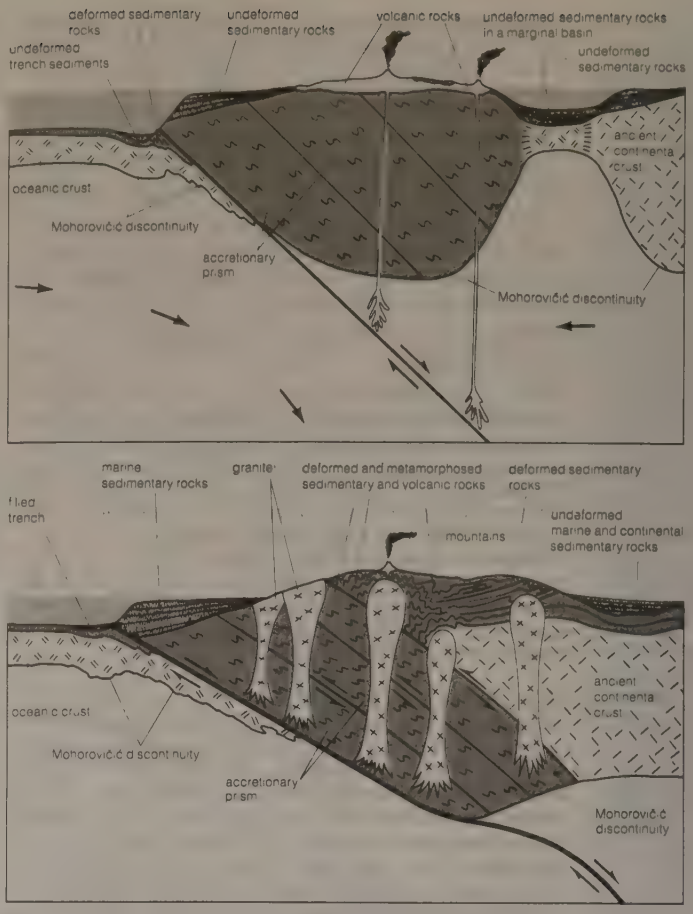

Figure 37: Cross section of a convergent plate boundary involving a collision between a continental plate and an oceanic plate in the vicinity of (top) an island arc and (bottom) a mountain arc.

margins by the descending oceanic slab. These types of folds and reverse faults occur in the northern Rockies.

Folds that occur where one continent collides with another may be the product of the shearing or compression caused by the shoving of one continent over another continent. Folds just above or just below such a plate margin along a subhorizontal plate boundary are formed by the drag associated with the shearing motion of the continents as they slide past each other. These folds are common in the Himalayas and in the central part of the southern Appalachians. Folds also may develop in front of a continent that is colliding with another continent. Such folds

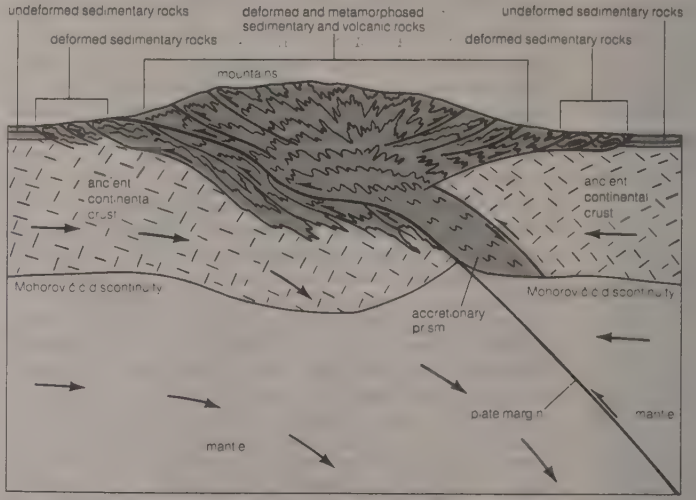

Figure 38: Cross section of a convergent plate boundary involving a collision between two continental plates near a Himalaya-type mountain chain.

are produced by the compressive force exerted in front of one continent that is overriding another continent. An example of folds of this variety is found in the Valley and Ridge Province in the southern Appalachians.

Formation of igneous rocks. Igneous rocks are formed by the crystallization of magma. Extrusive igneous rocks (volcanic rocks) are produced by the crystallization of magmas at the surface. Intrusive igneous rocks include those crystallized at shallow depth (hypabyssal igneous rocks), typically as dikes and sills, and those crystallized at medium to great depths (plutonic igneous rocks).

Igneous rocks are commonly found along both divergent and convergent plate boundaries. Those along divergent plate boundaries include volcanic, hypabyssal, and plutonic rocks. They form at spreading ridges and are part of the oceanic crust produced at these sites as plates move apart. Ophiolite sequences found on the continents are thought to be such oceanic crust brought to the Earth's surface by tectonic forces. The uppermost layer of igneous rocks in ophiolite sequences formed at divergent plate boundaries is composed of a basalt, a fine-grained, extrusive igneous rock of mafic composition (*i.e.*, rich in iron and magnesium). The next layer of igneous rock in ophiolite sequences is diabase, a mafic hypabyssal intrusive igneous rock. This type of diabase generally occurs as narrow dikes, more or less vertical intrusions that cut across sedimentary layering. These dikes are thought to have been the conduits that fed the basaltic flows in the overlying layer of pillow basalts. A layer of gabbro underlies the diabase in an ophiolite sequence. Gabbro is a mafic plutonic intrusive igneous rock that probably formed in a magma chamber beneath both the dikes and flows. A layer rich in the minerals olivine or serpentine underlies the gabbro and is thought to represent the mantle of the Earth. The Mohorovičić discontinuity separates the basalt, diabase, and gabbro of the oceanic crust from the underlying mantle rich in olivine and pyroxene.

Igneous activity at the spreading ridges

There is considerable variation in the amount of igneous activity along divergent plate boundaries at spreading ridges. Igneous activity is appreciably more intense in the vicinity of hot spots than elsewhere along divergent plate boundaries. A hot spot is an area in which igneous activity, particularly volcanism, is greater than average. Some hot spots are thought to be underlain by a mantle plume (a column of hot, partially molten rock emanating from the mantle). Iceland is an example of such a hot spot.

Hot spots

The igneous rocks formed along divergent plate boundaries also include those emplaced on or within continental crust. During the initial stage of the separation of two continents, continental crust is uplifted and faulted beneath the rising convection currents that cause the continents to pull apart. Basaltic magmas rise along such fractures and crystallize as volcanic rocks from flows or as dikes and sills if they form shallow intrusions. Such igneous rocks are often preserved in fault basins paralleling the continental margin and occur along with thick sequences of sedimentary rocks (Figure 36). An example of igneous and sedimentary rocks preserved in such a fault basin are the deposits of the Newark Series and rocks of a similar age found in the Newark and Gettysburg basins in the northeastern United States. These deposits and the fault basins in which they occur were formed when North America and Asia began to separate from Gondwanaland.

The origin of igneous rocks at divergent plate boundaries is presumably related to convection currents thought to rise under spreading ridges at the boundaries. As mantle material (composed of the rock peridotite) rises under the ridges, pressure is released on this material. Because the material is already hot and because a decrease in pressure tends to lower the melting temperature of rock, the rising peridotite begins to melt, or if it is already partly molten, the percentage of melt increases. When the amount of peridotite melt reaches 25 percent or so, the melt starts to separate from the solid, and the magma rises to form the igneous rocks at the divergent plate boundaries.

Igneous rocks also occur at convergent plate boundaries, both adjacent to subduction zones where oceanic plates move beneath continental plates and where two continental plates collide. Volcanic and intrusive varieties form along the so-called ring of fire bordering the Pacific Basin. Mt. St. Helens, Mt. Fuji, and the volcanoes of the Andes Mountains are examples of volcanoes that occur adjacent to subducting plate margins. The volcanic rocks in such areas include basalt, rhyolite (a sialic volcanic rock, rich in silicon and aluminum), and andesite (a rock intermediate in composition between basalt and rhyolite). Andesitic volcanic rocks are thought to form due to the partial melting of mantle material in the continental plate above the plate margin in the presence of a significant amount of water (Figure 37, top). The water may have been released from the oceanic plate that is being subducted beneath the continental plate. Magmas that form the volcanic rocks adjacent to subduction zones also may be produced by the frictional (shear-strain) heating of the rocks along the plate margin. This heating results from the frictional resistance generated along the plate margin as the oceanic plate moves past the continental plate.

Volcanic and intrusive igneous rocks in regions of convergence

Plutonic igneous rocks also form adjacent to subduction zones where an oceanic plate moves under a continental plate. Some of these plutonic rocks (gabbros and diorites) comprise the same magmas that formed the volcanic rocks of basaltic-to-andesitic composition. Intrusions of granite (sialic intrusive igneous rocks), however, often form very large bodies called batholiths. Granitic batholiths are thought by most, but not all, geologists to have been produced by the partial melting of material in the lower crust along subduction zones at convergent plate boundaries (Figure 37, bottom). Studies of the isotopic composition of strontium from batholiths found adjacent to subduction zones indicate that some batholiths (*e.g.*, the Sierra Nevada Batholith) were formed by the partial melting of sedimentary and volcanic rocks that were added onto the continental margin by accretion within the past 1,000,000,000 years, while others (*e.g.*, the Idaho Batholith) were produced by partial melting of rather ancient continental material more than 1,500,000,000 years old. After such a partial melt forms, it rises in the crust and provides materials for batholiths and volcanic flows or volcanic ash.

Origin of granitic batholiths

Igneous rocks found adjacent to plate margins where two continents converge tend to be of sialic composition and comprise granitic intrusions (including granite batholiths) and rhyolitic extrusions (both volcanic flows and volcanic ash). These sialic magmas are thought to have been formed primarily by the partial melting of crustal rocks near subducting plate margins. The heat necessary to partially melt crustal rocks along plate margins may have come from frictional heating as well as from hot rocks in the lower crust of the continental plate overlying the plate margin. This situation prevails in the Himalayas.

Metamorphism. Metamorphism requires heat and/or pressure to transform a sedimentary or an igneous rock into a metamorphic rock. Such a change involves an increase in grain size, formation of new minerals, gain or loss of water, and/or an increase in the degree of bonding of the mineral grains. Metamorphism can be either of two types: regional or contact. Regional metamorphism involves areas of very large extent (a few thousand to hundreds of thousands of square kilometres), while contact metamorphism is restricted to areas adjacent to igneous intrusions such as batholiths. Contact metamorphism can occur anywhere igneous intrusions occur. Regional metamorphism occurs principally along divergent and convergent plate boundaries. Metamorphism along divergent plate boundaries results in the conversion of basalts, diabases, or gabbros to greenstones or amphibolites. The greenstones are produced as a result of the heat furnished by the upwelling convection currents beneath the boundaries.

Regional and contact metamorphism

Regional metamorphism also may take place at convergent plate boundaries either where an oceanic plate moves under a continental plate along a subduction zone or where two continents collide. Regional metamorphism adjacent to subduction zones may occur beneath the plate margin in the underlying oceanic plate or above the plate margin in the overlying continental plate.

In cases where regional metamorphism occurs on the descending edge of an oceanic plate, sedimentary and volcanic rocks such as shales, sandstones, limestones, and basalts are converted into schists, quartzites, marbles,

greenstones, amphibolites, blueschists, and other metamorphic rocks (Figure 37, top). Some of these rocks (*e.g.*, the blueschists) show evidence of having been metamorphosed under relatively high pressures and low-to-moderate temperatures. Such conditions prevail wherever sedimentary and volcanic rocks on oceanic crust are carried rapidly beneath a continental plate. An increase in temperature in these areas is produced by frictional heating caused by the drag of one plate past the other and by heat from the overlying continental plate. An increase in pressure within the rocks is caused by the weight of the overlying rocks in the continental plate and stresses (overpressures) developed during the shearing of rocks along the plate margin. Distinct manifestations of metamorphism beneath plate margins along subduction zones are evident in many rocks bordering the Pacific Basin—*e.g.*, in the blueschists of the Franciscan Formation of the California Coast Ranges.

Regional metamorphism in the continental plate above the plate margin near subduction zones typically involves conditions of relatively high temperatures and low-to-medium pressures. Metamorphic rocks produced under such conditions include schists, marbles, quartzites, and amphibolites. The causes of the pressure increase during the metamorphism in areas of collision between two continents are both the weight of the continent above the plate margin and the stresses built up during the shearing of rocks along plate margins (Figure 38). Examples of areas affected by this type of metamorphism include the Himalayas and the Grenville Province in Canada.

Mountain building. Mountains are areas that have been uplifted as a result of either the thickening of the Earth's crust or the heating of the crust and upper mantle that causes an expansion of these layers. Mountain building occurs along both divergent and convergent plate boundaries.

The mid-oceanic ridge system

The mid-oceanic ridge system is located along divergent plate boundaries. This system is an undersea chain of mountains that extends up to one-third the width of the oceans in which it is found. The crust under the ridges has about the same thickness as the crust in the adjacent ocean basins. Thus, the uplift of the mid-oceanic ridges is not due to a thickening of the crust but rather to the heating of the crust and upper mantle beneath the ridges. This heating is presumably caused by the rising convection currents underlying mid-oceanic ridges.

Mountains also are formed in areas underlain by continental crust along divergent plate boundaries where two continents are just beginning to pull apart from each other. Such mountains form because of uplift caused by heating of the crust and mantle under the continents. This heating is attributable to the formation of a convection current beneath the continents, the current being the force that causes the landmasses to start separating. The mountains presently bordering the Red Sea in Africa and Saudi Arabia are representative of those formed in this fashion.

The mountains bordering the Pacific Basin formed along convergent plate boundaries where an oceanic plate moved under a continental plate along a zone of subduction. Compression of the continental plate by the descending oceanic plate resulted in the thickening of the crust, especially in the Rockies and Andes, and this crustal thickening produced the mountains. In some places the crust has been thickened from an average of 35 kilometres to as much as 70 kilometres and in the process produced the uplift necessary for mountain building.

Mountains that formed as a result of continent–continent collisions include the Appalachians and the Himalayas, along with the adjacent Plateau of Tibet. These mountains may have been created by the movement of one continental margin beneath another, which caused the thickness of the crust in the affected areas to double. For example, the thickness of the crust in southern India measures roughly 35 kilometres, but its thickness under the Plateau of Tibet north of the Himalayas is about 70 kilometres.

Intraplate activity. Although most tectonic activity takes place along plate boundaries, some occurs within plates. Much of this intraplate activity occurs along aulacogens and plume traces. An aulacogen can be defined as a failed third arm of a spreading ridge. Aulacogens commonly intersect a divergent plate margin at an angle of about 120°, and they form just as two continents begin to separate. They intersect plate margins at the site of the upwelling of a mantle plume (Figure 40). They are regions of tension within a plate and are commonly manifested in the form of grabens. Aulacogens often are filled with thick sequences of sedimentary and volcanic rocks, and volcanoes are usually located along them. The volcanic activity develops in response to upwelling mantle material beneath aulacogens. This material, however, does not rise with enough velocity to cause plate separation, only plate stretching. As apparent from Figure 39, the East African Rift System is an excellent example of an active aulacogen. This rift system intersects the margin of the African Plate at a plume located at the southern end of the Red Sea in the vicinity of the Afar Triangle.

Aulacogens

When a plate moves over a mantle plume, rocks that may be part of a volcano are carried away from the plume in the direction of plate motion. Plumes located within a plate produce a chain of volcanic islands and seamounts (submarine volcanoes) extending in one direction away from the plume. The age of the volcanic rocks and of the volcanoes generally increases away from the plume. Such a chain of volcanic islands and seamounts is called an aseismic ridge (a ridge without earthquakes), or plume trace.

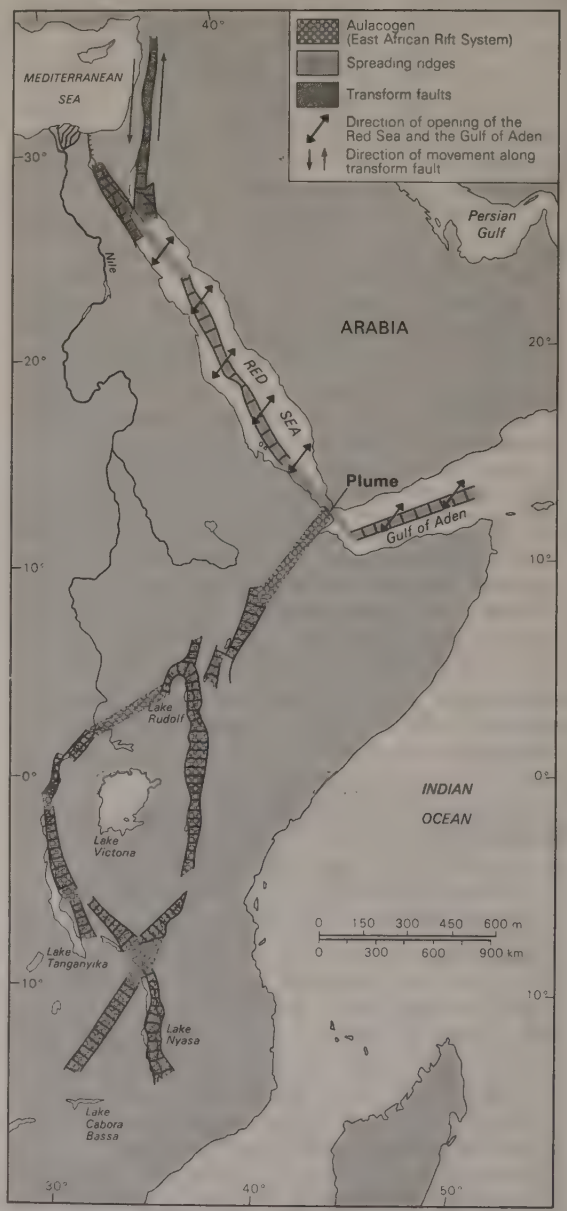

Figure 39: The major active aulacogen occurring along the East African Rift System.

Plume traces

The Hawaiian and Emperor Seamount chain is representative of this kind of structure. If a plume is located on a spreading ridge, as many are, two plume traces will form and extend in opposite directions away from the spreading ridge (Figure 40). Examples of such plume traces include a chain of volcanic islands extending westward away from the East Pacific Rise through Tuamoto Island and another volcanic island chain extending eastward through Easter Island away from the rise. Much of the volcanic activity along a plume trace formed by a plume on a spreading ridge is concentrated at the crest of the ridge, but a significant amount of volcanic activity along many such plume traces occurs within a plate after the plate has moved off the plume. Volcanic activity on Ascension Island, Easter Island, Pitcairn Island, and Tristan da Cunha is illustrative of this type of intraplate volcanism along a plume trace ending at a plate margin.

Convection theory

The cause of plate motions. Plates are thought to move in response to the movement of convection currents. These currents cause a vertical transfer of heat through a mass movement of material. In the Earth, the material that is moving vertically is mantle material, which contains about 5 percent magma between crystalline solids. This amount of liquid allows the mantle material to move more easily than if it were entirely solid.

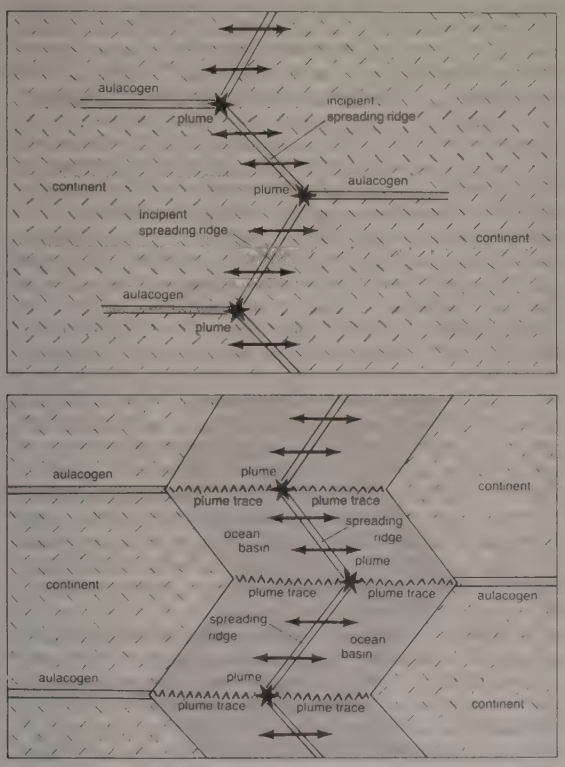

Figure 40: The development of aulacogens, plumes, and plume traces during the separation of two continents. Here, the process is shown in two stages.

The configuration of convection currents within the mantle is controversial. Some Earth scientists believe that convection within the mantle resembles convection cells observed within Newtonian liquids. Because the mantle is largely solid, however, it is unlikely that this type of convection would occur. Convection within a plastic solid would instead be expected to result in rising hot dikes. Such dikes are presumed to move upward under the influence of gravity and as they rise push plates apart, thereby providing the principal mechanism for plate movement. Some plates may move partially as a result of the pull of the relatively cool descending slab as it sinks down under the influence of gravity. Slab pull, however, cannot be the dominant force driving the plates because there are several very large plates that do not have a descending slab attached to them. Such plates include the North American and Eurasian plates.

To determine the configuration of the convection currents that move the plates, it is necessary to consider changes in the size of the plates. At the present time the plates bordering the Atlantic and Indian oceans (the North American, South American, Eurasian, Indian-Australian, African, and Antarctic plates) are increasing in area and volume as the continents drift away from the Mid-Atlantic and Mid-Indian ridges. As the continents move, the area of the Atlantic and Indian ocean basins increases. At the same time the plates bordering the Pacific Ocean (*e.g.*, the Pacific, Nazca, and Juan de Fuca plates) are decreasing in area and volume as the continents move toward the centre of the Pacific Basin. Hence, the area of the Pacific Basin is decreasing. In order for the plates to change in size, there must be a transfer of material from some plates to others. It is likely that material is transferred from the Pacific Plate to the Indian Plate by a movement of material from the subduction zone north of New Zealand to the Mid-Indian Ridge and from the subduction zone west of South America on the eastern part of the Nazca Plate to the Mid-Atlantic Ridge (Figure 41). Many convection models do not show such a transfer of material, but this transfer is necessary if plates do change in size as indicated above.

Convection currents are thought to rise unusually high under mid-oceanic ridges, and these are regions that exhibit a great deal of volcanic activity. Both these features would be expected to occur over a rising convection current. As the plates are forced apart by such currents, new oceanic crust is created at the ridges, and the ridges move away from the continents. For example, the Mid-Atlantic Ridge is moving westward away from Africa, the Southwest Indian Ridge southeastward from the continent, and the Mid-Indian Ridge northeastward from it. Geometry requires that as these ridges move away from Africa, they increase in length. Plumes located on these ridges move radially away from Africa. Because the ridges are increasing in length, the distance between the plumes located on them increases as well.

Energy sources for convection. Measurements of temperature in deep mines and oil wells indicate that there is a substantial temperature increase with depth. In part, this is due to the weight of overlying rocks. Such temperature increases are not accompanied by a change in heat content and are referred to as adiabatic temperature increases. Convection within the Earth occurs only if the temperature increase with depth exceeds the adiabatic temperature increase. Temperature increases of this kind are called super-adiabatic temperature increases.

Super-adiabatic temperature increases

The Earth has within it a super-adiabatic temperature increase. The energy sources causing this temperature increase include (1) the decay of long-lived radioactive (unstable) isotopes, such as uranium-235, uranium-238, and potassium-40; (2) the change of part of the Earth's core from a liquid to a solid; (3) the original heat from the time when the Earth formed, including heat produced by the impact of meteorites during the growth of the planet; and (4) the flexing of the Earth during tidal interaction between the Earth, Sun, and Moon (especially if the Earth and Moon were significantly closer together in the past).

Evidence for polar wandering, continental drift, and seafloor spreading. Polar wandering, continental drift, and seafloor spreading are all consequences of plate movements. Polar wandering is the movement of a continent relative to the rotational poles or spin axis of the Earth. Continental drift is the movement of one continent relative to another continent, and seafloor spreading is the movement of one block of seafloor relative to another block of seafloor. Evidence for both polar wandering and continental drift comes from matching continental outlines, paleoclimatology, paleontology, stratigraphy, structural geology, and paleomagnetism. The concept of seafloor spreading is supported by the age of volcanic islands and the age of the oldest sediments on the seafloor, as well as by the study of the magnetism of the seafloor.

Matching continental outlines. Early geographers making maps of the South Atlantic Ocean were probably the first to notice the similarity of the outlines of South America and Africa and to wonder if these two continents might have been together at one time. It was not until

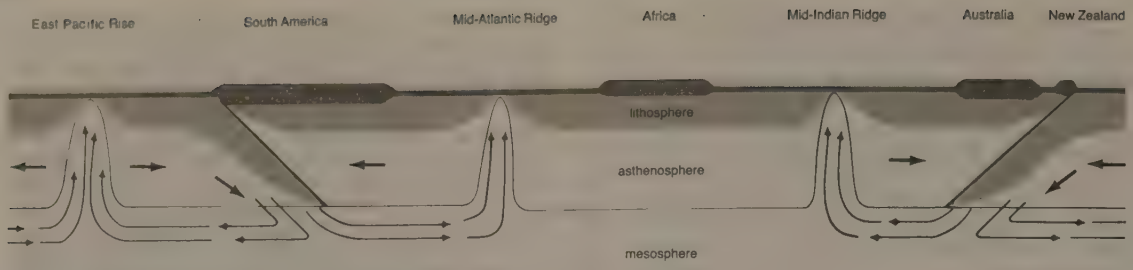

Figure 41: Schematic cross section showing one of various possible models for convection within the Earth.

the early 20th century, however, that Alfred Wegener of Germany used the geography of the Atlantic coastlines, along with geologic and paleontological data, to suggest that all the continents were once connected. In his major work *Die Entstehung der Kontinente und Ozeane* (1915; *The Origin of Continents and Oceans*), he postulated that a single supercontinent called Pangaea existed some 320,000,000 to 286,000,000 years ago and that its subsequent breakup gave rise to the present-day continents.

Wegener's hypothesis

Actually, the fit of the coastlines of South America and Africa is only fair. These continents fit together very well, however, if they are matched at the 1,000-metre depth contour. In recent years computers have been used to match the outlines of all continents bordering the Atlantic Ocean (Figure 42). Such computer fits are made so that continental outlines at different depths are matched with a minimum area of overlap and a minimum area of gap between the continents. Similar fits of continents may be made around the Indian Ocean as well.

Paleoclimatological data. Alfred Wegener was a meteorologist who was particularly interested in the study of ancient climates (paleoclimatology). He noticed that sedimentary rocks indicative of having been deposited in warm climates are now found in cold climates and vice versa. He felt that these observations were best explained if the continents had moved relative to each other and if the poles had moved relative to those continents.

Glaciation is indicated by the presence of till containing grooved, striated, and faceted pebbles, along with cobbles and boulders that lie on grooved, striated, and polished bedrock. Till deposited by continental ice sheets 420,000,000 years ago is found in the Sahara, and similar unconsolidated sediments dating back 280,000,000 years occur near the present-day Equator in southern India and in central Africa. The direction of ice movement, indicated by the orientation of such features as roche moutonnées is away from rather than toward the present ocean basins. If the continents were moved back together into a single landmass, however, one would find that the glacial ice was directed from the continental interior toward the oceans 280,000,000 years ago (Figure 43). Furthermore, the centre from which the ice appears to have radiated is very close to the location of the south rotational pole, as determined from paleomagnetic studies (see below).

Indications of warm climate such as the presence of thick salt deposits, fossil sand dunes, and fossil coral reefs are commonly found in the arctic regions of Canada and northern Greenland. These are easily explained if the continents moved relative to the poles, as is indicated from paleomagnetic studies. Shifts of the continents relative to the poles are also strongly suggested by changes in the direction of prevailing winds. The orientation of fossil sand dunes 250,000,000 years old in England and the southwestern United States indicate that these areas were in a belt of prevailing easterlies at that time but are now located in a belt of prevailing westerlies. Paleomagnetic data show that England and the southwestern United States lay close to the Equator 250,000,000 years ago. Today, winds blow from the east near the Equator, and so it is likely that those two geographic areas shifted relative to the poles during the last 250,000,000 years.

From *Scientific American* (April 1968), p. 52

Figure 42: Computer-generated "best fit" of the continents bordering the Atlantic Ocean, as proposed by the British geophysicists E.C. Bullard, J.E. Everett, and A.G. Smith. The fit was made at the 1,000-metre (500-fathom) submarine depth contour. The matching was done in such a way that the area of the overlaps (in black) of the continental margins equals the area of the gaps (in white) between them.

Paleontological research. Many paleontological observations are most easily explained by continental drift and/or polar wandering. For example, fossils of the freshwater reptile *Mesosaurus,* which lived 270,000,000 years ago, are found only in South America and Africa. The reptile's bone structure was such that it probably could not have swum across the Atlantic, but if South America and Africa had been connected then, *Mesosaurus* could easily have moved from one continent to another.

Distribution of fossils

Terrestrial reptiles that lived 225,000,000 years ago in Antarctica closely resemble those of the same age found in Africa. These two areas are not connected at the present time, but they may have been joined together 225,000,000 years ago. Furthermore, fossils from plants belonging to the genus *Glossopteris* and related genera that lived in South America, Africa, Australia, India, and Antarctica 270,000,000 years ago are remarkably similar, leading to the hypothesis that these landmasses once constituted the supercontinent Gondwanaland (see above).

Stratigraphic findings. The sequence of layered rocks on the landmasses that constituted Gondwanaland is strikingly similar for those time periods when the landmasses are believed to have been together. In these areas glacial deposits, for example, are overlain by coal-bearing shales and sandstones containing fossils of *Glossopteris* and *Mesosaurus*, which are in turn overlain by thick sequences of mafic (basaltic) volcanic rocks.

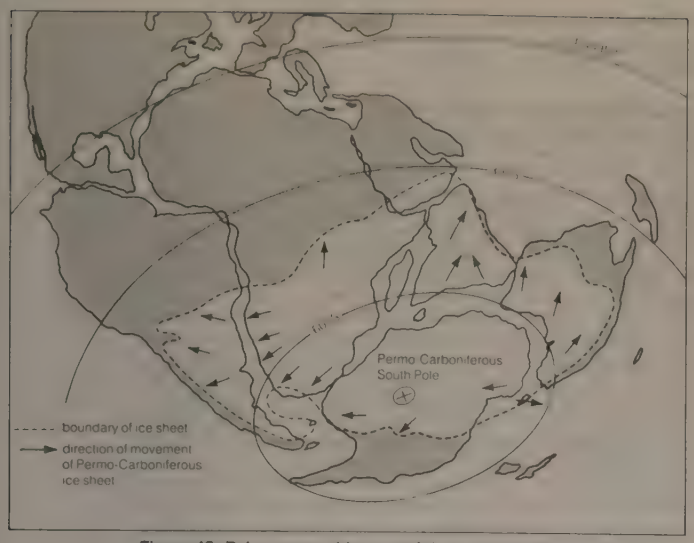

Figure 43: Paleogeographic map of the continents during the Late Carboniferous and Early Permian periods showing the inferred distribution of continental ice sheets.

Results of structural geologic studies. Deformed rocks typically occur in long, linear belts along the trend of present or past mountain belts. In many parts of the world, mountain belts end rather abruptly at the edges of continents and commonly occur in pairs located on opposite sides of an ocean. The Appalachian mountain belt, for example, extends from Georgia and Alabama through southeastern Pennsylvania, New England, and the Maritime Provinces of Canada to Newfoundland. The Caledonian mountain belt, which, like the Appalachians, formed about 450,000,000 to 350,000,000 years ago, extends from the island of Spitsbergen north of Norway through Norway, Scotland, and England to Ireland. Another part of the Caledonian belt is located on the east coast of Greenland. When all the continents are put back together in a single landmass, the Appalachian and Caledonian mountains are connected into a single mountain range (Figure 43).

Similarities between mountain belts

Paleomagnetism. All rocks contain what is referred to as natural remanent magnetism. This property is due to magnetism acquired by iron-bearing minerals during the cooling and crystallization of an igneous rock, to the formation of iron-bearing minerals at low temperatures during the weathering of previously formed minerals, to the rotation of iron-bearing minerals during their deposition in a sedimentary rock, or to post-depositional processes such as the striking of rocks by lightning.

Natural remanent magnetism

The direction and inclination of the magnetic field of rocks of different ages have been measured from rock samples collected from all over the world, and this information can be used to ascertain the location of the Earth's magnetic pole at the time when those rocks were formed. The direction of the magnetic field of a given rock sample indicates the direction in which the magnetic pole of the Earth lay when the rock formed, while the inclination of the magnetic field of the rock indicates how far away from the collection site the magnetic pole was located. For example, if the inclination of the magnetic field is nearly horizontal, the magnetic pole of the Earth must have been 90 great circle degrees away from the collection site because the site was near the magnetic equator. On the other hand, if the inclination of the magnetic field of a rock is vertical, the collection site would have been located at or near the Earth's magnetic pole at the time of rock formation. It is assumed that if enough rock samples of a given age are averaged together, the average position of the magnetic pole will be the same as the average position of the Earth's rotational pole. Thus, paleomagnetic poles provide the location of the planet's rotational pole.

If paleomagnetic poles for a given continent are plotted on a map of the world, it is found that they tend to lie along lines called apparent polar wandering (APW) paths (Figure 44). Evidently Europe drifted eastward relative to North America sometime during the past 550,000,000 years. If Europe were moved westward back to the position that it occupied before the continents began to separate from one another (as indicated by matching continental outlines across the Atlantic), the APW path for Europe from 200,000,000 to 400,000,000 years ago agrees with the equivalent APW path for North America. Thus, Europe and North America were together in the arrangement indicated by matching of continental outlines during that time interval.

Age of oceanic islands. One of the earliest indications that some blocks of seafloor are moving relative to other such blocks was that while the age of young volcanic islands or seamounts shows no relationship to distance from spreading mid-oceanic ridges, old features of this sort are never found near the ridges. This relationship can be readily explained if new seafloor is created at the crests of mid-oceanic ridges and with time this seafloor, along with the volcanic islands, is carried off the ridges as the seafloor spreads. In this case, there can be no old volcanic islands or seamounts near the ridges because the oceanic crust on which volcanic islands sit is relatively young near the ridges.

Evidence for the creation of new oceanic crust at the mid-oceanic ridges

Age of the oldest marine sediments. Samples of sediments have been recovered as a result of deep drilling and piston coring from many parts of the world's ocean basins. These sediments have been dated by means of the fossils they contain. Such studies have shown that no old sediments are present (at least in the areas sampled) near mid-oceanic ridges. Moreover, the studies also have revealed that the age of the oldest sediments in the ocean basins generally increases away from the ridges. This relationship is exactly what one would expect if new oceanic crust is being formed at the ridges and is being carried away from them as the seafloor spreads.

Marine magnetics. The most convincing evidence supporting the concept of seafloor spreading comes from the study of the magnetism of the ocean floor. For a number of years, measurements have been made in the oceans of the total intensity of the magnetic field of the Earth using instruments called magnetometers, which are generally towed behind ships (see above). These measurements have shown that there are numerous magnetic anomalies (deviations from the average intensity of the Earth's magnetic field) in the ocean basins. Such anomalies are positive if

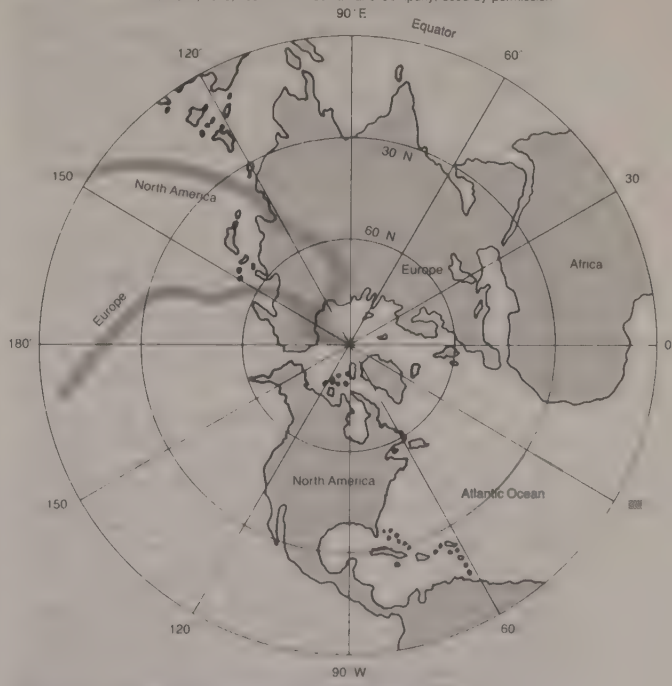

Figure 44: Comparison of apparent polar wandering (APW) paths of North America and Europe. The fact that the APW paths do not coincide indicates that these continents have moved with respect to each other.

the magnetic field is greater than average, and they are negative if the field is less than average.

Magnetic anomalies along the mid-oceanic ridges

Magnetic surveys over the crests of mid-oceanic ridges indicate that magnetic anomalies occur in long bands paralleling the axis of the ridges and that the anomalies are symmetrical with respect to the ridges.

Rocks that are relatively young and that have a magnetism roughly parallel to the present-day magnetic field of the Earth are said to be normally magnetized, whereas those that are relatively young and exhibit a magnetism that is 180° different from the current magnetic field are said to be reversely magnetized. Young, normally magnetized rocks in the Northern Hemisphere have a magnetic field that is oriented down and directed to the north. Young, reversely magnetized rocks in the Northern Hemisphere have a magnetic field that is oriented up and directed to the south. As mentioned earlier, studies of the age and polarity of volcanic rocks collected from all over the world indicate that the Earth's magnetic field reversed itself a number of times in the past. Nearly all samples of volcanic rocks younger than 690,000 years are normally magnetized, corresponding to the fact that the Earth's magnetic field has been normal for that time period. Volcanic rock samples 690,000 to 890,000 years old are reversely magnetized, reflective of the reversed orientation of the Earth's magnetic field during that interval.

Vine-Matthews hypothesis

In 1963 the British geophysicists Frederick J. Vine and Drummond H. Matthews proposed that the magnetic anomalies in oceanic regions were produced as a result of the extrusion of volcanic rocks on the ocean floor during times of alternating normal and reversed magnetic fields. In this model, the magnetism of lavas extruded when the magnetic field of the Earth is normal adds to the magnetism generated in the planet's liquid core, resulting in a positive magnetic anomaly. By contrast, the magnetism of lavas extruded when the Earth's field is reversed subtracts from the magnetism produced in the core, giving rise to a negative magnetic anomaly.

The Vine-Matthews hypothesis provides an explanation for the symmetry of the magnetic anomalies over mid-oceanic ridges. As magnetized lavas are erupted during the formation of new oceanic crust at the ridge crests, the resulting volcanic rocks are carried away from the crests in both directions. The pattern of the magnetic anomalies is virtually identical to the pattern of the geomagnetic time scale. These observations can only be explained if volcanic activity occurred principally at the crests of mid-oceanic ridges and if seafloor spreading occurred during alternating periods of normal and reversed polarity of the Earth. Moreover, magnetic profiles calculated by computers using assumed strips of alternating normally and reversely magnetized volcanic rocks matched observed magnetic profiles almost exactly, providing further support for the model set forth by Vine and Matthews. Structure and composition of the solid Earth: DAVID G. SMITH (ed.), *The Cambridge Encyclopedia of Earth Sciences* (1981), is a highly readable, illustrated collection of articles on the Earth's surface and interior. Two collections of articles from *Scientific American* are *The Dynamic Earth* (1983), on the geologic processes occurring inside and around the planet; and ROBERT DECKER and BARBARA DECKER (eds.), *Volcanoes and the Earth's Interior* (1982), on volcanoes and the rocks occurring in the mantle. MINORU OZIMA, *The Earth: Its Birth and Growth* (1981; originally published in Japanese, 1979), gives a general account of the evolution of the Earth based on geochemical research. MARTIN H.P. BOTT, *Interior of the Earth: Its Structure, Constitution, and Evolution*, 2nd ed. (1982), provides a thorough summary of the nature of the Earth's interior. Two works with a more technical slant are JEAN-CLAUDE DE BREMAECKER, *Geophysics, the Earth's Interior* (1985), an introductory textbook; and DONALD L. TURCOTTE and GERALD SCHUBERT, *Geodynamics: Applications of Continuum Physics to Geological Problems* (1982), a mathematical text on processes occurring within the Earth. See also G.C. BROWN and A.E. MUSSETT, *The Inaccessible Earth* (1981), on both geophysics and geochemistry.

(R.J.)

Major geologic features of the Earth's exterior: DAVID ALT, *Physical Geology: A Process Approach* (1982), is an up-to-date introduction to the principles of physical geology. DANIEL S. BARKER, *Igneous Rocks* (1983), discusses the characteristics of igneous rocks and their relationship to plate tectonics. MARLAND P. BILLINGS, *Structural Geology*, 3rd ed. (1972), is a classic introduction to structural geology, which describes the deformation of the Earth's crust. A. HALLAM, *A Revolution in the Earth Sciences: From Continental Drift to Plate Tectonics* (1973), is an excellent historical review of the development of ideas on continental drift, polar wandering, seafloor spreading, and plate tectonics. ARTHUR HOLMES, *Principles of Physical Geology*, 2nd rev. ed. (1965), is a beautifully written, though somewhat dated, introduction to physical geology. ROBLEY K. MATTHEWS, *Dynamic Stratigraphy: An Introduction to Sedimentation and Stratigraphy*, 2nd ed. (1984), relates the study of the sequence of layered rocks to plate tectonics. WILLIAM D. THORNBURY, *Principles of Geomorphology*, 2nd ed. (1969), is a classic account of the shaping of the Earth's surface by natural forces, including a description of the relationship between structural geology and landforms. TJEERD H. VAN ANDEL, *New Views on an Old Planet: Continental Drift and the History of Earth* (1985), is an excellent introduction to the ideas of continental drift, polar wandering, seafloor spreading, and plate tectonics from the viewpoint of an oceanographer. BRIAN F. WINDLEY, *The Evolving Continents*, 2nd ed. (1984), relates the geology of various parts of the Earth to plate tectonics and the Wilson cycle of ocean-basin formation. Studies of historical geology include DON L. EICHER, A. LEE MCALESTER, and MARCIA L. ROTTMAN, *The History of the Earth's Crust* (1984); and CARL K. SEYFERT and LESLIE A. SIRKIN, *Earth History and Plate Tectonics* (1979), which relates the history of the Earth to plate tectonics, especially to the Wilson cycle.

(C.K.S.)

The Earth Sciences

The broad aim of the Earth sciences is to understand the present features and the past evolution of the Earth and to use this knowledge, where appropriate, for the benefit of humankind. Thus the basic concerns of the Earth scientist are to observe, describe, and classify all the features of the Earth, whether characteristic or not, to generate hypotheses with which to explain their presence and their development, and to devise means of checking opposing ideas for their relative validity. In this way the most plausible, acceptable, and long-lasting ideas are developed.

The physical environment in which humans live includes not only the immediate surface of the solid Earth, but also the ground beneath it and the water and air above it. Early man was more involved with the practicalities of life than with theories, and thus his survival depended on his ability to obtain metals from the ground to produce, for example, alloys, such as bronze from copper and tin, for tools and armour, to find adequate water supplies for establishing dwelling sites, and to forecast the weather, which had a far greater bearing on human life in earlier times than it has today. Such situations represent the foundations of the three principal component disciplines of the modern Earth sciences—the geologic, hydrologic, and atmospheric—which form the tripartite framework of the present article.

The rapid development of science as a whole over the past century and a half has given rise to an immense number of specializations and subdisciplines, with the result that the modern Earth scientist, perhaps unfortunately, tends to know a great deal about a very small area of study but only a little about most other aspects of the entire field. It is therefore very important for the lay person and the researcher alike to be aware of the complex interlinking network of disciplines that make up the Earth sciences today, and that is the purpose of this article. Only when one is aware of the marvelous complexity of the Earth sciences and yet can understand the breakdown of the component disciplines is one in a position to select those parts of the subject that are of greatest personal interest.

It is worth emphasizing two important features that the three divisions of the Earth sciences have in common. First is the inaccessibility of many of the objects of study. Many rocks, as well as water and oil reservoirs, are at great depths in the Earth, while air masses circulate at vast heights above it. Thus the Earth scientist has to have a good three-dimensional perspective. Second, there is the fourth dimension: time. The Earth scientist is responsible for working out how the Earth evolved over millions of years. For example, what were the physical and chemical conditions operating on the Earth and the Moon 3,500,000,000 years ago? How did the oceans form, and how did their chemical composition change with time? How has the atmosphere developed? And finally, how did life on Earth begin, and from what did man evolve?

Today the Earth sciences are divided into many disciplines, which are themselves divisible into six groups:

(1) Those subjects that deal with the water and air at or above the solid surface of the Earth. These include the study of the water on and within the ground (hydrology), the glaciers and ice caps (glaciology), the oceans (oceanography), the atmosphere and its phenomena (meteorology), and the world's climates (climatology). In this article such fields of study are grouped under the hydrologic and atmospheric sciences and are treated separately from the geologic sciences, which focus on the solid Earth.

(2) Disciplines concerned with the physical-chemical makeup of the solid Earth, which include the study of minerals (mineralogy), the three main groups of rocks (igneous, sedimentary, and metamorphic petrology), the chemistry of rocks (geochemistry), the structures in rocks (structural geology), and the physical properties of rocks at the Earth's surface and in its interior (geophysics).

(3) The study of landforms (geomorphology), which is concerned with the description of the features of the present terrestrial surface and an analysis of the processes that gave rise to them.

(4) Disciplines concerned with the geologic history of the Earth, including the study of fossils and the fossil record (paleontology), the development of sedimentary strata deposited typically over millions of years (stratigraphy), and the isotopic chemistry and age dating of rocks (geochronology).

(5) Applied Earth sciences dealing with current practical applications beneficial to society. These include the study of fossil fuels (oil, natural gas, and coal); oil reservoirs; mineral deposits; geothermal energy for electricity and heating; the structure and composition of bedrock for the location of bridges, nuclear reactors, roads, dams, and skyscrapers and other buildings; hazards involving rock and mud avalanches, volcanic eruptions, earthquakes, and the collapse of tunnels; and coastal, cliff, and soil erosion.

(6) The study of the rock record on the Moon and the planets and their satellites (astrogeology). This field includes the investigation of relevant terrestrial features—namely, tektites (glassy objects resulting from meteorite impacts) and astroblemes (meteorite craters).

With such intergradational boundaries between the divisions of the Earth sciences (which, on a broader scale, also intergrade with physics, chemistry, biology, mathematics, and certain branches of engineering), researchers today must be versatile in their approach to problems. Hence, an important aspect of training within the Earth sciences is an appreciation of their multidisciplinary nature.

(B.F.W.)

This article is divided into the following sections:

History of the Earth sciences

ORIGINS IN PREHISTORIC TIMES

The origins of the Earth sciences lie in the myths and legends of the distant past. The creation story, which can be traced to a Babylonian epic of the 22nd century BC and which is told in the first chapter of Genesis, has proved most influential. The story is cast in the form of Earth history and thus was readily accepted as an embodiment of scientific as well as of theological truth.

Earth scientists later made innumerable observations of natural phenomena and interpreted them in an increasingly multidisciplinary manner. The Earth sciences, however, were slow to develop largely because the progress of science was constrained by whatever society would tolerate or support at any one time.

ANTIQUITY

Classification of rocks and minerals by Theophrastus

Geologic sciences. *Knowledge of Earth composition and structure.* The oldest known treatise on rocks and minerals is the *De lapidibus* ("On Stones") of the Greek philosopher Theophrastus (*c.* 372–*c.* 287 BC). Written probably in the early years of the 3rd century, this work remained the best study of mineral substances for almost 2,000 years. Although reference is made to some 70 different materials, the work is more an effort at classification than systematic description.

In early Chinese writings on mineralogy, stones and rocks were distinguished from metals and alloys, and further distinctions were made on the basis of colour and other physical properties. The speculations of Cheng Ssu-hsiao (died AD 1332) on the origin of ore deposits were more advanced than those of his contemporaries in Europe. In brief, his theory was that ore is deposited from groundwater circulating in subsurface fissures.

Speculations on earthquakes and volcanic eruptions

Ancient accounts of earthquakes and volcanic eruptions are sometimes valuable as historical records but tell little about the causes of these events. Aristotle (384–322 BC) and Strabo (64 BC–*c.* AD 21) held that volcanic explosions and earthquakes alike are caused by spasmodic motions of hot winds that move underground and occasionally burst forth in volcanic activity attended by Earth tremors. Classical and medieval ideas on earthquakes and volcanoes were brought together in William Caxton's *Mirrour of the World* (1480). Earthquakes are here again related to movements of subterranean fluids. Streams of water in the Earth compress the air in hidden caverns. If the roofs of the caverns are weak, they rupture, causing cities and castles to fall into the chasms; if strong, they merely tremble and shake from the heaving by the wind below. Volcanic action follows if the outburst of wind and water from the depths is accompanied by fire and brimstone from hell.

Chinese invention of the seismograph

The Chinese have the distinction of keeping the most faithful records of earthquakes and of inventing the first instrument capable of detecting them. Records of the dates on which major quakes rocked China date to 780 BC. To detect quakes at a distance, the mathematician, astronomer, and geographer Chang Heng (AD 78–139) invented what has been called the first seismograph.

Knowledge of Earth history. The occurrence of seashells embedded in the hard rocks of high mountains aroused the curiosity of early naturalists and eventually set off a controversy on the origin of fossils that continued through the 17th century. Xenophanes of Colophon (flourished *c.* 560 BC) was credited by later writers with observing that seashells occur "in the midst of earth and in mountains." He is said to have believed that these relics originated during a catastrophic event that caused the Earth to be mixed with the sea and then to settle, burying organisms in the drying mud. For these views Xenophanes is sometimes called the father of paleontology.

Petrified wood was described by Chinese scholars as early as the 9th century AD, and around 1080 Shen Kua cited fossilized plants as evidence for change in climate. Other kinds of fossils that attracted the attention of early Chinese writers include spiriferoid brachiopods ("stone swallows"), cephalopods, crabs, and the bones and teeth of reptiles, birds, and mammals. Although these objects were commonly collected simply as curiosities or for medicinal purposes, Shen Kua recognized marine invertebrate fossils for what they are and for what they imply historically. Observing seashells in strata of the T'ai-hang Shan range, he concluded that this region, though now far from the sea, must once have been a shore.

Formation of river deltas and alluvial plains

Knowledge of landforms and of land–sea relations. Changes in the landscape and in the position of land and sea related to erosion and deposition by streams were recognized by some early writers. The Greek historian Herodotus (*c.* 484–*c.* 426 BC) correctly concluded that the northward bulge of Egypt into the Mediterranean is caused by the deposition of mud carried by the Nile.

The early Chinese writers were not outdone by the Romans and Greeks in their appreciation of changes wrought by erosion. In the *Chin shu* ("History of the Chin Dynasty"), it is said of Tu Yü (AD 222–284) that when he ordered monumental stelae to be carved with the records of his successes, he had one buried at the foot of a mountain and the other erected on top. He predicted that in time they would likely change their relative positions, because the high hills will become valleys and the deep valleys will become hills.

Aristotle guessed that changes in the position of land and sea might be cyclical in character, thus reflecting some sort of natural order. If the rivers of a moist region should

build deltas at their mouths, he reasoned, seawater would be displaced and the level of the sea would rise to cover some adjacent dry region. A reversal of climatic conditions might cause the sea to return to the area from which it had previously been displaced and retreat from the area previously inundated. The idea of a cyclical interchange between land and sea was elaborated in the *Discourses of the Brothers of Purity*, a classic Arabic work written between AD 941 and 982 by an anonymous group of scholars at Basra (Iraq). The rocks of the lands disintegrate and rivers carry their wastage to the sea, where waves and currents spread it over the seafloor. There the layers of sediment accumulate one above the other, harden, and, in the course of time, rise from the bottom of the sea to form new continents. Then the process of disintegration and leveling begins again.

Hydrologic and atmospheric sciences. The only substance known to the ancient philosophers in its solid, liquid, and gaseous states, water is prominently featured in early theories about the origin and operations of the Earth. Thales of Miletus (*c.* 624–*c.* 545 BC) is credited with a belief that water is the essential substance of the Earth, and Anaximander of Miletus (*c.* 610–545 BC) held that water was probably the source of life. In the system proposed by Empedocles of Agrigentum (*c.* 490–430 BC), water shared the primacy Thales had given it with three other elements: fire, air, and earth. The doctrine of the four earthly elements was later embodied in the universal system of Aristotle and thereby influenced Western scientific thought until late in the 17th century.

Knowledge of the hydrologic cycle. The idea that the waters of the Earth undergo cyclical motions, changing from seawater to vapour to precipitation and then flowing back to the ocean, is probably older than any of the surviving texts that hint at or frame it explicitly.

The idea of the hydrological cycle developed independently in China as early as the 4th century BC and was explicitly stated in the *Lü-shih Ch'un Ch'iu* ("The Spring and Autumn Annals of Mr. Lü"), written in the 3rd century BC. A circulatory system of a different kind, involving movements of water on a large scale within the Earth, was envisioned by Plato (*c.* 428–348/347 BC). In one of his two explanations for the origin of rivers and springs, he described the Earth as perforated by passages connecting with Tartarus, a vast subterranean reservoir.

Origin of rivers, springs, and precipitation

A coherent theory of precipitation is found in the writings of Aristotle. Moisture on the Earth is changed to airy vapour by heat from above. Because it is the nature of heat to rise, the heat in the vapour carries it aloft. When the heat begins to leave the vapour, the vapour turns to water. The formation of water from air produces clouds. Heat remaining in the clouds is further opposed by the cold inherent in the water and is driven away. The cold presses the particles of the cloud closer together, restoring in them the true nature of the element water. Water naturally moves downward, and so it falls from the cloud as raindrops. Snow falls from clouds that have frozen.

In Aristotle's system the four earthly elements were not stable but could change into one another. If air can change to water in the sky, it should also be able to change into water underground.

The origin of the Nile. Of all the rivers known to the ancients, the Nile was most puzzling with regard to its sources of water. Not only does this river maintain its course up the length of Egypt through a virtually rainless desert, but it rises regularly in flood once each year.

Speculations on the strange behaviour of the Nile were many, varied, and mostly wrong. Thales suggested that the strong winds that blow southward over the delta in summertime hold back the flow of the river and cause the waters to rise upstream in flood. Oenopides of Chios (flourished *c.* 475 BC) thought that heat stored in the ground during the winter dries up the underground veins of water so that the river shrinks. In the summer the heat disappears, and water flows up into the river, causing floods. In the view of Diogenes of Apollonia (flourished *c.* 435 BC), the Sun controls the regimen of the stream. The idea that the Nile waters connect with the sea is an old one, tracing back to the geographic concepts of Hecataeus of Miletus (*c.* 520 BC). Reasonable explanations related the discharge of the Nile to precipitation in the headwater regions, as snow (Anaxagoras of Clazomenae, *c.* 500–428 BC) or from rain that filled lakes supposed to have fed the river (Democritus of Abdera, *c.* 460–*c.* 357 BC). Eratosthenes (*c.* 276–194 BC), who had prepared a map of the Nile Valley southward to the latitude of modern Khartoum, anticipated the correct answer when he reported that heavy rains had been observed to fall in the upper reaches of the river and that these were sufficient to account for the flooding.

Knowledge of the tides. The tides of the Mediterranean, being inconspicuous in most places, attracted little notice from Greek and Roman naturalists. Poseidonius (135–50 BC) first correlated variations in the tides with phases of the Moon.

By contrast, the tides along the eastern shores of Asia generally have a considerable range and were the subject of close observation and much speculation among the Chinese. In particular, the tidal bore on the Ch'ien-t'ang Chiang (Ch'ien-t'ang River) near Hang-chou attracted early attention; with its front ranging up to 3.7 metres in height, this bore is one of the largest in the world. As early as the 2nd century BC, the Chinese had recognized a connection between tides and tidal bores and the lunar cycle.

Construction of *qanats*

Prospecting for groundwater. Although the origin of the water in the Earth that seeps or springs from the ground was long the subject of much fanciful speculation, the arts of finding and managing groundwater were already highly developed in the 8th century BC. The construction of long, hand-dug underground aqueducts (*qanats*) in Armenia and Persia represents one of the great hydrologic achievements of the ancient world. After some 3,000 years *qanats* are still a major source of water in Iran.

In the 1st century BC, Vitruvius (Marcus Vitruvius Pollio), a Roman architect and engineer, described methods of prospecting for groundwater in his *De architectura libri decem* (*The Architecture of Marcus Vitruvius Pollio, in Ten Books*). To locate places where wells should be dug, he recommended looking for spots where mist rises in early morning. More significantly, Vitruvius had learned to associate different quantities and qualities of groundwater with different kinds of rocks and topographic situations.

After the inspired beginnings of the ancient Greeks, Romans, Chinese, and Arabs, little or no new information was collected, and no new ideas were produced throughout the Middle Ages, appropriately called the Dark Ages. It was not until the Renaissance in the early 16th century that the Earth sciences began to develop again.

THE 16TH–18TH CENTURIES

Geologic sciences. *Ore deposits and mineralogy.* A common belief among alchemists of the 16th and 17th centuries held that metalliferous deposits were generated by heat emanating from the centre of the Earth but activated by the heavenly bodies.

The German scientist Georgius Agricola has with much justification been called the father of mineralogy. Of his seven geologic books, *De natura fossilium* (1546; "On Natural Fossils") contains his major contributions to mineralogy and, in fact, has been called the first textbook on that subject. In Agricola's time and well into the 19th century, "fossil" was a term that could be applied to any object dug from the Earth. Thus Agricola's classification of fossils provided pigeonholes for organic remains, such as ammonites, and for rocks of various kinds in addition to minerals. Individual kinds of minerals, their associations and manners of occurrence, are described in detail, many for the first time.

Agricola's *De natura fossilium*

With the birth of analytical chemistry toward the latter part of the 18th century, the classification of minerals on the basis of their composition at last became possible. The German geologist Abraham Gottlob Werner was one of those who favoured a chemical classification in preference to a "natural history" classification based on external appearances. His list of several classifications, published posthumously, recognized 317 different substances ordered in four classes.

Paleontology and stratigraphy. During the 17th century

the guiding principles of paleontology and historical geology began to emerge in the work of a few individuals. Nicolaus Steno, a Danish scientist and theologian, presented carefully reasoned arguments favouring the organic origin of what are now called fossils. Also, he elucidated three principles that made possible the reconstruction of certain kinds of geologic events in a chronological order. In his *Canis carcariae dissectum caput* (1667; "Dissected Head of a Dog Shark"), he concluded that large tongue-shaped objects found in the strata of Malta were the teeth of sharks, whose remains were buried beneath the seafloor and later raised out of the water to their present sites. This excursion into paleontology led Steno to confront a broader question. How can one solid body, such as a shark's tooth, become embedded in another solid body, such as a layer of rock? He published his answers in 1669 in a paper entitled "De solido intra naturaliter contento dissertationis" ("A Preliminary Discourse Concerning a Solid Body Enclosed by Processes of Nature Within a Solid"). Steno cited evidence to show that when the hard parts of an organism are covered with sediment, it is they and not the aggregates of sediment that are firm. Consolidation of the sediment into rock may come later, and, if so, the original solid fossil becomes encased in solid rock. He recognized that sediments settle from fluids layer by layer to form strata that are originally continuous and nearly horizontal. His principle of superposition of strata states that in a sequence of strata, as originally laid down, any stratum is younger than the one on which it rests and older than the one that rests upon it.

Steno's principles of superposition, continuity, and horizontality of strata

In 1667 and 1668 the English physicist Robert Hooke read papers before the Royal Society in which he expressed many of the ideas contained in Steno's works. Hooke argued for the organic nature of fossils. Elevation of beds containing marine fossils to mountainous heights he attributed to the work of earthquakes. Streams attacking these elevated tracts wear down the hills, fill depressions with sediment, and thus level out irregularities of the landscape.

Earth history according to Werner and James Hutton. The two major theories of the 18th century were the Neptunian and the Plutonian. The Neptunists, led by Werner and his students, maintained that the Earth was originally covered by a turbid ocean. The first sediments deposited over the irregular floor of this universal ocean formed the granite and other crystalline rocks. Then as the ocean began to subside, "Stratified" rocks were laid down in succession. The "Volcanic" rocks were the youngest; Neptunists took small account of volcanism and thought that lava was formed by the burning of coal deposits underground.

Neptunists and the universal ocean

The Scottish scientist James Hutton, leader of the Plutonists, viewed the Earth as a dynamic body that functions as a heat machine. Streams wear down the continents and deposit their waste in the sea. Subterranean heat causes the outer part of the Earth to expand in places, uplifting the compacted marine sediments to form new continents. Hutton recognized that granite is an intrusive igneous rock and not a primitive sediment as the Neptunists claimed. Intrusive sills and dikes of igneous rock provide evidence for the driving force of subterranean heat. Hutton viewed great angular unconformities separating sedimentary sequences as evidence for past cycles of sedimentation, uplift, and erosion. His *Theory of the Earth,* published as an essay in 1788, was expanded to a two-volume work in 1795. John Playfair, a professor of natural philosophy, defended Hutton against the counterattacks of the Neptunists, and his *Illustrations of the Huttonian Theory* (1802) is the clearest contemporary account of Plutonist theory.

Hydrologic sciences. The idea that there is a circulatory system within the Earth, by which seawater is conveyed to mountaintops and there discharged, persisted until early in the 18th century. Two questions left unresolved by this theory were acknowledged even by its advocates. How is seawater forced uphill? How is the salt lost in the process?

The rise of subterranean water. René Descartes supposed that the seawater diffused through subterranean channels into large caverns below the tops of mountains. The Jesuit philosopher Athanasius Kircher in his *Mundus subterraneus* (1664; "Subterranean World") suggested that the tides pump seawater through hidden channels to points of outlet at springs. To explain the rise of subterranean water beneath mountains, the chemist Robert Plot appealed to the pressure of air, which forces water up the insides of mountains. The idea of a great subterranean sea connecting with the ocean and supplying it with water together with all springs and rivers was resurrected in 1695 in John Woodward's *Essay towards a Natural History of the Earth and Terrestrial Bodies.*

Ideas on the origin of springs

The French Huguenot Bernard Palissy maintained, to the contrary, that rainfall is the sole source of rivers and springs. In his *Discours admirables* (1580; *Admirable Discourses*) he described how rainwater falling on mountains enters cracks in the ground and flows down along these until, diverted by some obstruction, it flows out on the surface as springs. Palissy scorned the idea that seawater courses in veins to the tops of mountains. For this to be true, sea level would have to be higher than mountaintops—an impossibility. In his *Discours* Palissy suggested that water would rise above the level at which it was first encountered in a well provided the source of the groundwater came from a place higher than the bottom of the well. This is an early reference to conditions essential to the occurrence of artesian water, a popular subject among Italian hydrologists of the 17th and 18th centuries.

Explanation of artesian flow

In the latter part of the 17th century, Pierre Perrault and Edmé Mariotte conducted hydrologic investigations in the basin of the Seine River that established that the local annual precipitation was more than ample to account for the annual runoff.

Evaporation from the sea. The question remained as to whether the amount of water evaporated from the sea is sufficient to account for the precipitation that feeds the streams. The English astronomer-mathematician Edmond Halley measured the rate of evaporation from pans of water exposed to the air during hot summer days. Assuming that this same rate would obtain for the Mediterranean, Halley calculated that some 5,280,000,000 tons of water are evaporated from this sea during a summer day. Assuming further that each of the nine major rivers flowing into the Mediterranean has a daily discharge 10 times that of the Thames, he calculated that a daily inflow of fresh water back into that sea would be 1,827,000,000 tons, only slightly more than a third of the amount lost by evaporation. Halley went on to explain what happens to the remainder. A part falls back into the sea as rain before it reaches land. Another part is taken up by plants.

Halley's explanation of ocean salinity

In the course of the hydrologic cycle, Halley reasoned, the rivers constantly bring salt into the sea in solution, but the salt is left behind when seawater evaporates to replenish the streams with rainwater. Thus the sea must be growing steadily saltier.

Atmospheric sciences. *Water vapour in the atmosphere.* After 1760 the analytical chemists at last demonstrated that water and air are not the same substance in different guises. Long before this development, however, investigators had begun to draw a distinction between water vapour and air. Otto von Guericke, a German physicist and engineer, produced artificial clouds by releasing air from one flask into another one from which the air had been evacuated. A fog then formed in the unevacuated flask. Guericke concluded that air cannot be turned into water, though moisture can enter the air and later be condensed into water. Guericke's experiments, however, did not answer the question as to how water enters the atmosphere as vapour. In "Les Météores" ("Meteorology," an essay published in the book *Discours de la methode* in 1637), Descartes envisioned water as composed of minute particles that were elongate, smooth, and separated by a highly rarified "subtle matter."

The same uncertainty as to how water gets into the air surrounded the question as to how it remains suspended as clouds. A popular view in the 18th century was that clouds are made of countless tiny bubbles that float in air. Guericke had suggested that the fine particles in his artificial clouds were bubbles. Other observers professed to have seen bubble-shaped particles of water vapour rising from warm water or hot coffee.

Cloud formation and motion

Pressure, temperature, and atmospheric circulation. If clouds are essentially multicompartmented balloons, their motions could be explained by the movements of winds blowing on them. Descartes suggested that the winds might blow upward as well as laterally, causing the clouds to rise or at least preventing them from descending. In 1749 Benjamin Franklin explained updrafts of air as due to local heating of the atmosphere by the Sun. Sixteen years later the Swiss-German mathematical physicist Johann Heinrich Lambert described the conditions necessary for the initiation of convection currents in the atmosphere. He reasoned that rising warm air flows into bordering areas of cooler air, increasing their downward pressure and causing their lower layers to flow into ascending currents, thus producing circulation.

Importance of the barometer

The fact that Lambert could appeal to changes in air pressure to explain circulation reflects an important change from the view still current in the late 16th century that air is weightless. This misconception was corrected after 1643 with the invention of the mercury barometer. It was soon discovered that the height of the barometer varied with the weather, usually standing at its highest during clear weather and falling to the lowest on rainy days.

Toward the end of the 18th century it was beginning to be understood that variations in the barometer must be related to the general motion and circulation of the atmosphere. That these variations could not be due solely to changes in humidity was the conclusion of the Swiss scientist Horace Bénédict de Saussure in his *Essais sur l'hygrométrie* (1783; "Essay on Hygrometry"). From experiments with changes of water vapour and pressure in air enclosed in a glass globe, Saussure concluded that changes in temperature must be immediately responsible for variations of the barometer and that these in turn must be related to the movement of air from one place to another.

THE 19TH CENTURY

Geologic sciences. *Crystallography and the classification of minerals and rocks.* The French scientist René-Just Häuy, whose treatises on mineralogy and crystallography appeared in 1801 and 1822, respectively, has been credited with advancing mineralogy to the status of a science and with establishing the science of crystallography. From his studies of the geometric relationships between planes of cleavage, he concluded that the ultimate particles forming a given species of mineral have the same shape and that variations in crystal habit reflect differences in the ways identical molecules are put together. In 1814 Jöns Jacob Berzelius of Sweden published a system of mineralogy offering a comprehensive classification of minerals based on their chemistry. Berzelius recognized silica as an acid and introduced into mineralogy the group known as silicates. At mid-century the American geologist James Dwight Dana's *System of Mineralogy*, in its third edition, was reorganized around a chemical classification, which thereafter became standard for handbooks.

Optical studies of rocks

The development of the polarizing microscope and the technique for grinding sections of rocks so thin as to be virtually transparent came in 1827 from studies of fossilized wood by William Nicol. In 1849 Clifton Sorby showed that minerals viewed in thin section could be identified by their optical properties, and soon afterward improved classifications of rocks were made on the basis of their mineralogic composition. The German geologist Ferdinand Zirkel's *Mikroscopische Beschaffenheit der Mineralien und Gesteine* (1873; "The Microscopic Nature of Minerals and Rocks") contains one of the first mineralogic classifications of rocks and marks the emergence of microscopic petrography as an established branch of science.

William Smith and faunal succession. In 1683 the zoologist Martin Lister proposed to the Royal Society that a new sort of map be drawn showing the areal distribution of the different kinds of British "soiles" (vegetable soils and underlying bedrock). The work proposed by Lister was not accomplished until 132 years later, when William Smith published his *Geologic Map of England and Wales with Part of Scotland* (1815). A self-educated surveyor and engineer, Smith had the habit of collecting fossils and making careful note of the strata that contained them. He discovered that the different stratified formations in England contain distinctive assemblages of fossils. His map, reproduced on a scale of five miles to the inch, showed 20 different rock units, to which Smith applied local names in common use—*e.g.*, London Clay and Purbeck Beds. In 1816 Smith published a companion work, *Strata Identified by Organized Fossils*, in which the organic remains characteristic of each of his rock units were illustrated. His generalization that each formation is "possessed of properties peculiar to itself [and] has the same organized fossils throughout its course" is the first clear statement of the principle of faunal sequence, which is the basis for worldwide correlation of fossiliferous strata into a coherent system. Smith thus demonstrated two kinds of order in nature: order in the spatial arrangement of rock units and order in the succession of ancient forms of life.

Smith's principle of faunal sequence was another way of saying that there are discontinuities in the sequences of fossilized plants and animals. These discontinuities were interpreted in two ways: as indicators of episodic destruction of life or as evidence for the incompleteness of the fossil record. Baron Georges Cuvier of France was one of the more distinguished members of a large group of naturalists who believed that paleontological discontinuities bore witness to sudden and widespread catastrophes. Cuvier's skill at comparative anatomy enabled him to reconstruct from fragmentary remains the skeletons of large vertebrate animals found at different levels in the Cenozoic sequence of northern France. From these studies he discovered that the fossils in all but the youngest deposits belong to species now extinct. Moreover, these extinct species have definite ranges up and down in the stratigraphic column. Cuvier inferred that the successive extinctions were the result of convulsions that caused the strata of the continents to be dislocated and folded and the seas to sweep across the continents and just as suddenly subside.

Cuvier's catastrophic viewpoint

Charles Lyell and uniformitarianism. In opposition to the catastrophist school of thought, the British geologist Charles Lyell proposed a uniformitarian interpretation of geologic history in his *Principles of Geology* (3 vols., 1830–33). His system was based on two propositions: the causes of geologic change operating include all the causes that have acted from the earliest time; and these causes have always operated at the same average levels of energy. These two propositions add up to a "steady-state" theory of the Earth. Changes in climate have fluctuated around a mean, reflecting changes in the position of land and sea. Progress through time in the organic world is likewise an illusion, the effect of an imperfect paleontological record. The main part of the *Principles* was devoted less to theory than to procedures for inferring events from rocks; and for Lyell's clear exposition of methodology his work was highly regarded throughout its many editions, long after the author himself had abandoned antiprogressivist views on the development of life.

Louis Agassiz and the ice age. Huge boulders of granite resting upon limestone of the Jura Mountains were subjects of controversy during the 18th and early 19th centuries. Saussure described these in 1779 and called them erratics. He concluded that they had been swept to their present positions by torrents of water. Saussure's interpretation was in accord with the tenets of diluvial geologists, who interpreted erratics and sheets of unstratified sediment (till or drift) spread over the northern parts of Europe and North America as the work of the "Deluge."

Argument for large-scale glaciation of Europe and Asia

In 1837 the Swiss zoologist and paleontologist Louis Agassiz delivered a startling address before the Helvetian Society, proposing that, during a geologically recent stage of refrigeration, glacial ice had covered Eurasia from the North Pole to the shores of the Mediterranean and Caspian. Wherever erratics, till, and striated pavements of rock occur, sure evidence of this recent catastrophe exists. The reception accorded this address was glacial, too, and Alexander von Humboldt advised Agassiz to return to his fossil fishes. Instead, he began intensive field studies and in 1840 published his *Études sur les glaciers* ("Studies of Glaciers"), demonstrating that Alpine glaciers had been far more extensive in the past. That same year he visited the British Isles in the company of Buckland and extended

the glacial doctrine to Scotland, northern England, and Ireland. In 1846 he carried his campaign to North America and there found additional evidence for an ice age.

Geologic time and the age of the Earth. By mid-century the fossiliferous strata of Europe had been grouped into systems arrayed in chronological order. The stratigraphic column, a composite of these systems, was pieced together from exposures in different regions by application of the principles of superposition and faunal sequence. Time elapsed during the formation of a system became known as a period, and the periods were grouped into eras: the Paleozoic (Cambrian through Permian periods), Mesozoic (Triassic, Jurassic, and Cretaceous periods), and Cenozoic (Tertiary and Quaternary periods).

Charles Darwin's *Origin of Species* (1859) offered a theoretical explanation for the empirical principle of faunal sequence. The fossils of the successive systems are different not only because parts of the stratigraphic record are missing but also because most species have lost in their struggles for survival and also because those that do survive evolve into new forms over time. Darwin borrowed two ideas from Lyell and the uniformitarians: the idea that geologic time is virtually without limit and the idea that a sequence of minute changes integrated over long periods of time produce remarkable changes in natural entities.

Limitations based on the Earth's heat production

The evolutionists and the historical geologists were embarrassed when, beginning in 1864, William Thomson (later Lord Kelvin) attacked the steady-state theory of the Earth and placed numerical strictures on the length of geologic time. The Earth might function as a heat machine, but it could not also be a perpetual motion machine. Assuming that the Earth was originally molten, Thomson calculated that not less than 20,000,000 and not more than 400,000,000 years could have passed since the Earth first became a solid body. Other physicists of note put even narrower limits on the Earth's age ranging down to 15,000,000 or 20,000,000 years. All these calculations, however, were based on the common assumption, not always explicitly stated, that the Earth's substance is inert and hence incapable of generating new heat. Shortly before the end of the century this assumption was negated by the discovery of radioactive elements that disintegrate spontaneously and release heat to the Earth in the process.

Concepts of landform evolution. The scientific exploration of the American West following the end of the Civil War yielded much new information on the sculpture of the landscape by streams. John Wesley Powell in his reports on the Colorado River and Uinta Mountains (1875, 1876) explained how streams may come to flow across mountain ranges rather than detour around them. The Green River does not follow some structural crack in its gorge across the Uinta Mountains; instead it has cut its canyon as the mountain range was slowly bowed up. Given enough time, streams will erode their drainage basins to plains approaching sea level as a base. Grove Karl Gilbert's *Report on the Geology of the Henry Mountains* (1877) offered a detailed analysis of fluvial processes. According to Gilbert all streams work toward a graded condition, a state of dynamic equilibrium that is attained when the net effect of the flowing water is neither erosion of the bed nor deposition of sediment, when the landscape reflects a balance between the resistance of the rocks to erosion and the processes that are operative upon them. After 1884 William Morris Davis developed the concept of the geographical cycle, during which elevated regions pass through successive stages of dissection and denudation characterized as youthful, mature, and old. Youthful landscapes have broad divides and narrow valleys. With further denudation the original surface on which the streams began their work is reduced to ridgetops. Finally in the stage of old age, the region is reduced to a nearly featureless plain near sea level or its inland projection. Uplift of the region in any stage of this evolution will activate a new cycle. Davis' views dominated geomorphic thought until well into the 20th century, when quantitative approaches resulted in the rediscovery of Gilbert's ideas.

Gilbert's statement of dynamic equilibrium

Gravity, isostasy, and the Earth's figure. Discoveries of regional anomalies in the Earth's gravity led to the realization that high mountain ranges have underlying deficiencies in mass about equal to the apparent surface loads represented by the mountains themselves. In the 18th century the French scientist Pierre Bouguer had observed that the deflections of the pendulum in Peru are much less than they should be if the Andes represent a load perched on top of the Earth's crust. Similar anomalies were later found to obtain along the Himalayan front. To explain these anomalies it was necessary to assume that beneath some depth within the Earth pressures are hydrostatic (equal on all sides). If excess loads are placed upon the crust, as by addition of a continental ice cap, the crust will sink to compensate for the additional mass and will rise again when the load is removed. The tendency toward general equilibrium maintained through vertical movements of the Earth's outer layers was called isostasy in 1899 by Clarence Edward Dutton of the United States.

Concept of geosyncline and mountain building

Evidence for substantial vertical movements of the crust was supplied by studies of regional stratigraphy. In 1883 another American geologist, James Hall, had demonstrated that Paleozoic rocks of the folded Appalachians were several times as thick as sequences of the same age in the plateaus and plains to the west. It was his conclusion that the folded strata in the mountains must have accumulated in a linear submarine trough that filled with sediment as it subsided. Downward crustal flexures of this magnitude came to be called geosynclines.

Hydrologic sciences. *Darcy's law.* Quantitative studies of the movement of water in streams and aquifers led to the formulation of mathematical statements relating discharge to other factors. Henri-Philibert-Gaspard Darcy, a French hydraulic engineer, was the first to state clearly a law describing the flow of groundwater. Darcy's experiments, reported in 1856, were based on the ideas that an aquifer is analogous to a main line connecting two reservoirs at different levels and that an artesian well is like a pipe drawing water from a main line under pressure. His investigations of flow through stratified beds of sand led him to conclude that the rate of flow is directly proportional to the energy loss and inversely proportional to the length of the path of flow. Another French engineer, Arsène-Jules-Étienne-Juvénal Dupuit, extended Darcy's work and developed equations for underground flow toward a well, for the recharge of aquifers, and for the discharge of artesian wells. Philip Forchheimer, an Austrian hydrologist, introduced the theory of functions of a complex variable to analyze the flow by gravity of underground water toward wells and developed equations for determining the critical distance between a river and a well beyond which water from the river will not move into the well.

Surface water discharge. A complicated empirical formula for the discharge of streams resulted from the studies of Andrew Atkinson Humphreys and Henry Larcom Abbot in the course of the Mississippi Delta Survey of 1851–60. Their formula contained no term for roughness of channel and on this and other grounds was later found to be inapplicable to the rapidly flowing streams of mountainous regions. In 1869 Emile-Oscar Ganguillet and Rudolph Kutter developed a more generally applicable discharge equation following their studies of flow in Swiss mountain streams. Toward the end of the century, systematic studies of the discharge of streams had become common. In the United States the Geological Survey, following its establishment in 1879, became the principal agency for collecting and publishing data on discharge, and by 1906 stream gauging had become nationwide.

Foundations of oceanography. In 1807 Thomas Jefferson ordered the establishment of the U.S. Coast Survey (later Coast and Geodetic Survey and now the National Ocean Survey). Modeled after British and French agencies that had grown up in the 1700s, the agency was charged with the responsibilities of hydrographic and geodetic surveying, studies of tides, and preparation of charts. Beginning in 1842 the U.S. Navy undertook expansive oceanographic operations through its office of charts and instruments. Lieut. Matthew Fontaine Maury promoted international cooperation in gathering meteorologic and hydrologic data at sea. In 1847 Maury compiled the first wind and current charts for the North Atlantic and in 1854 issued the first depth map to 4,000 fathoms (7,300

Maury's compilation of oceanographic data

metres). His *Physical Geography of the Sea* (1855) is generally considered the first oceanographic textbook.

The voyage of the *Beagle* (1831–36) is remembered for Darwin's biological and geologic contributions. From his observations in the South Pacific, Darwin formulated a theory for the origin of coral reefs, which with minor changes has stood the test of time. He viewed the fringing reefs, barrier reefs, and atolls as successive stages in a developmental sequence. The volcanic islands around which the reef-building organisms are attached slowly sink, but at the same time the shallow-water organisms that form the reefs build their colonies upward so as to remain in the sunlit layers of water. With submergence of the island, what began as a fringing reef girdling a landmass at last becomes an atoll enclosing a lagoon.

Laying telegraphic cables across the Atlantic called for investigations of the configuration of the ocean floor, of the currents that sweep the bottom, and of the benthonic animals that might damage the cables. The explorations of the British ships *Lightning* and *Porcupine* in 1868 and 1869 turned up surprising oceanographic information. Following closely upon these voyages, the *Challenger* was authorized to determine "the conditions of the Deep Sea throughout the Great Ocean Basins."

The *Challenger* expedition (1872–76)

The *Challenger* left port in December of 1872 and returned in May 1876, after logging 127,600 kilometres (68,890 nautical miles). Under the direction of Wyville Thomson, Scottish professor of natural history, it occupied 350 stations scattered over all oceans except the Arctic. The work involved in analyzing the information gathered during the expedition was completed by Thomson's shipmate Sir John Murray, and the results filled 50 large volumes. Hundreds of new species of marine organisms were described, including new forms of life from deep waters. The temperature of water at the bottom of the oceans was found to be nearly constant below the 2,000-fathom level, averaging about 2.5° C (36.5° F) in the North Atlantic and 2° C (35° F) in the North Pacific. Soundings showed wide variations in depths of water, and from the dredgings of the bottom came new types of sediment—red clay as well as oozes made predominantly of the minute skeletons of foraminifera, radiolarians, or diatoms. Improved charts of the principal surface currents were produced, and the precise location of many oceanic islands was determined for the first time. Seventy-seven samples of seawater were taken at different stations from depths ranging downward to about 1.5 kilometres. The German-born chemist Wilhelm Dittmar conducted quantitative determinations of the seven major constituents (other than the hydrogen and oxygen of the water itself)—namely, sodium, calcium, magnesium, potassium, chloride, bromide, and sulfate. Surprisingly, the percentages of these components turned out to be nearly the same in all samples.

Tidal analysis and prediction

Efforts to analyze the rise and fall of the tides in mathematical terms reflecting the relative and constantly changing positions of Earth, Moon, and Sun, and thus to predict the tides at particular localities, has never been entirely successful because of local variations in configuration of shore and seafloor. Nevertheless, harmonic tidal analysis gives essential first approximations that are essential to tidal prediction. In 1884 a mechanical analog tidal prediction device was invented by William Ferrel of the U.S. Coast and Geodetic Survey, and improved models were used until 1965, when the work of the analog machines was taken over by electronic computers.

Atmospheric sciences. *Composition of the atmosphere.* Studies of barometric pressure by the British chemist and physicist John Dalton led him to conclude that evaporation and condensation of vapour do not involve chemical transformations. The introduction of vapour into the air by evaporation must change the average specific gravity of the air column and, without altering the height of that column, will change the reading of the barometer. In 1857 Rudolf Clausius, a German physicist, clarified the mechanics of evaporation in his kinetic theory of gases. Evaporation occurs when more molecules of a liquid are leaving its surface than returning to it, and the higher the temperature the more of these escaped molecules will be in space at any one time.

Sampling the atmosphere by balloon

Following the invention of the hot-air balloon by the Montgolfier brothers in 1783, balloonists produced some useful information on the composition and movements of the atmosphere. In 1804 the celebrated French chemist Joseph-Louis Gay-Lussac ascended to about 7,000 metres, took samples of air, and later determined that the rarefied air at that altitude contained the same percentage of oxygen (21.49 percent) as the air on the ground. Austrian meteorologist Julius von Hann, working with data from balloon ascents and climbing in the Alps and Himalayas, concluded in 1874 that about 90 percent of all the water vapour in the atmosphere is concentrated below 6,000 metres—from which it follows that high mountains can be barriers against the transport of water vapour.

Understanding of clouds, fog, and dew. Most of the names given to clouds (cirrus, cumulus, stratus, nimbus, and their combinations) were coined in 1803 by the English meteorologist Luke Howard. Howard's effort was not simply taxonomic; he recognized that clouds reflect in their shapes and changing forms "the general causes which effect all the variations of the atmosphere."

After Guericke's experiments it was widely believed that water vapour condenses into cloud as soon as the air containing it cools to the dew point. That this is not necessarily so was proved by Paul-Jean Coulier of France from experiments reported in 1875. Coulier found that the sudden expansion of air in glass flasks failed to produce an artificial cloud if the air in the system was filtered through cotton wool. He concluded that dust in the air was essential to the formation of cloud in the flask.

Discovery of condensation nuclei

From about the mid-1820s, efforts were made to classify precipitation in terms of the causes behind the lowering of temperature. In 1841 the American astronomer-meteorologist Elias Loomis recognized the following causes: warm air coming into contact with cold earth or water, responsible for fog; mixing of warm and cold currents, which commonly results in light rains; and sudden transport of air into high regions, as by flow up a mountain slope or by warm currents riding over an opposing current of cold air, which may produce heavy rains.

Recognition of the revolving nature of storms

Observation and study of storms. Storms, particularly tropical revolving storms, were subjects of much interest. As early as 1697 some of the more spectacular features of revolving storms were recorded in William Dampier's *New Voyage Round the World.* On July 4, 1687, Dampier's ship survived the passage of what he called a "tuffoon" off the coast of China. The captain's vivid account of this experience clearly describes the calm central eye of the storm and the passage of winds from opposite directions as the storm moved past. In 1828 Heinrich Wilhelm Dove, a Prussian meteorologist, recognized that tropical revolving storms are traveling systems with strong winds moving counterclockwise in the Northern Hemisphere and clockwise in the Southern Hemisphere. The whirlwind character of these storms was independently established by the American meteorologist William C. Redfield in the case of the September hurricane that struck New England in 1821. He noted that in central Connecticut the trees had been toppled toward the northwest, whereas some 80 kilometres westward they had fallen in the opposite direction. Redfield identified the belt between the Equator and the tropics as the region in which hurricanes are generated, and he recognized how the tracks of these storms tend to veer eastward when they enter the belt of westerly winds at about latitude 30° N. In 1849 Sir William Reid, a British meteorologist and military engineer, studied the revolving storms that occur south of the Equator in the Indian Ocean and confirmed that they have reversed rotations and curvatures of path compared with those of the Northern Hemisphere. Capt. Henry Piddington subsequently investigated revolving storms affecting the Bay of Bengal and Arabian Sea, and in 1855 he named these cyclones in his *Sailor's Horn-book for the Laws of Storms in all Parts of the World.*

Consideration of energy sources

Beginning in 1835 James Pollard Espy, an American meteorologist, began extensive studies of storms from which he developed a theory to explain their sources of energy. Radially convergent winds, he believed, cause the air to rise in their area of collision. Upward movement of moist

air is attended by condensation and precipitation. Latent heat released through the change of vapour to cloud or water causes further expansion and rising of the air. The higher the moist air rises the more the equilibrium of the system is disturbed, and this equilibrium cannot be restored until moist air at the surface ceases to flow toward the ascending column.

That radially convergent winds are not necessary to the rising of large air masses was demonstrated by Loomis in the case of a great storm that passed across the northeastern United States in December 1836. From his studies of wind patterns, changes of temperature, and changes in barometric pressure, he concluded that a cold northwest wind had displaced a wind blowing from the southeast by flowing under it. The southeast wind made its escape by ascending from the Earth's surface. Loomis had recognized what today would be called a frontal surface.

Weather and climate. Modern meteorology began when the daily weather map was developed as a device for analysis and forecasting, and the instrument that made this kind of map possible was the electromagnetic telegraph. In the United States the first telegraph line was strung in 1844 between Washington, D.C., and Baltimore. Concurrently with the expansion of telegraphic networks, the physicist Joseph Henry arranged for telegraph companies to have meteorological instruments in exchange for current data on weather telegraphed to the Smithsonian Institution. Some 500 stations had joined this cooperative effort by 1860. The Civil War temporarily prevented further expansion, but, meanwhile, a disaster of a different order had accelerated development of synoptic meteorology in Europe. On Nov. 14, 1854, an unexpected storm wrecked British and French warships off Balaklava on the Crimean peninsula. Had word of the approaching storm been telegraphed to this port in the Black Sea, the ships might have been saved. This mischance led in 1856 to the establishment of a national storm-warning service in France. In 1863 the Paris Observatory began publishing the first weather maps in modern format.

The first national weather service in the United States began operations in 1871 as an agency of the Department of War. The initial objective was to provide storm warnings for the Gulf and Atlantic coasts and the Great Lakes. In 1877 forecasts of temperature changes and precipitation averaged 74 percent in accuracy, as compared with 79 percent for cold-wave warnings. After 1878 daily weather maps were published.

Synoptic meteorology made possible the tracking of storm systems over wide areas. In 1868 the British meteorologist Alexander Buchan published a map showing the travels of a cyclonic depression across North America, the Atlantic, and into northern Europe. In the judgment of Sir Napier Shaw, Buchan's study marks the entry of modern meteorology, with "the weather map as its main feature and forecasting its avowed object."

Mapping regional variations

In addition to weather maps, a variety of other kinds of maps showing regional variations in the components of weather and climate were produced. In 1817 Alexander von Humboldt published a map showing the distribution of mean annual temperatures over the greater part of the Northern Hemisphere. Humboldt was the first to use isothermal lines in mapping temperature. Buchan drew the first maps of mean monthly and annual pressure for the entire world. Published in 1869, these maps added much to knowledge of the general circulation of the atmosphere. In 1886 Léon-Philippe Teisserenc de Bort of France published maps showing mean annual cloudiness over the Earth for each month and the year. The first world map of precipitation showing mean annual precipitation by isohyets was the work of Loomis in 1882. This work was further refined in 1899 by the maps of the British cartographer Andrew John Herbertson, which showed precipitation for each month of the year.

Although the 19th century was still in the age of meteorologic and climatological exploration, broad syntheses of old information thus kept pace with acquisition of the new fairly well. For example, Julius Hann's massive *Handbuch der Klimatologie* ("Handbook of Climatology"), first issued in 1883, is mainly a compendium of works published in the *Meteorologische Zeitschrift* ("Journal of Meteorology"). The *Handbuch* was kept current in revised editions until 1911, and this work is still sometimes called the most skillfully written account of world climate.

THE 20TH CENTURY: MODERN TRENDS AND DEVELOPMENTS

The impact of technological advances and the theory of plate tectonics

Geologic sciences. The development of the geologic sciences in the 20th century has been influenced by two major "revolutions." The first involves dramatic technological advances that have resulted in vastly improved instrumentation, the prime examples being the many types of highly sophisticated computerized devices. The second is centred on the development of the plate tectonics theory, which is the most profound and influential conceptual advance the Earth sciences have ever known.

Modern technological developments have affected all the different geologic disciplines. Their impact has been particularly notable in such activities as radiometric dating, experimental petrology, crystallography, chemical analysis of rocks and minerals, micropaleontology, and seismological exploration of the Earth's deep interior.

Radiometric dating. In 1905, shortly after the discovery of radioactivity, the American chemist Bertram Boltwood suggested that lead is one of the disintegration products of uranium, in which case the older a uranium-bearing mineral the greater should be its proportional part of lead. Analyzing specimens whose relative geologic ages were known, Boltwood found that the ratio of lead to uranium did indeed increase with age. After estimating the rate of this radioactive change he calculated that the absolute ages of his specimens ranged from 410,000,000 to 2,200,000,000 years. Though his figures were too high by about 20 percent, their order of magnitude was enough to dispose of the short scale of geologic time proposed by Lord Kelvin.

Versions of the modern mass spectrometer were invented in the early 1920s and 1930s, and during World War II the device was improved substantially to help in the development of the atomic bomb. Soon after the war, Harold C. Urey and G.J. Wasserburg applied the mass spectrometer to the study of geochronology. This device separates the different isotopes of the same element and can measure the variations in these isotopic abundances to within one part in 10,000. By determining the amount of the parent and daughter isotopes present in a sample and by knowing their rate of radioactive decay (each radioisotope has its own decay constant), the isotopic age of the sample can be calculated. For dating minerals and rocks, investigators commonly use the following couplets of parent and daughter isotopes: thorium-232–lead-208, uranium-235–lead-207, samarium-147–neodymium-143, rubidium-87–strontium-87, potassium-40–argon-40, and argon-40–argon-39.

Application of the mass spectrometer to geochronology

Such techniques have had an enormous impact on scientific knowledge of Earth history because precise dates can now be obtained on rocks in all orogenic (mountain) belts ranging in age from the early Archean (about 3,800,000,000 years old) to the late Tertiary (roughly 20,000,000 years old). The oldest sedimentary and igneous rocks in the world are found at Isua in western Greenland; they have an isotopic age of approximately 3,800,000,000 years—a fact first established in 1972 by Stephen Moorbath of the University of Oxford. Also by extrapolating backward in time to a situation when there was no lead that had been produced by radiogenic processes, a figure of about 4,600,000,000 years is obtained for the minimum age of the Earth. This figure is of the same order as ages obtained for certain meteorites and lunar rocks.

Experimental study of rocks. Experimental petrology began with the work of Jacobus Henricus van't Hoff, one of the founders of physical chemistry. Between 1896 and 1908 he elucidated the complex sequence of chemical reactions attending the precipitation of salts (evaporites) from the evaporation of seawater. Van't Hoff's aim was to explain the succession of mineral salts present in Permian rocks of Germany. His success at producing from aqueous solutions artificial minerals and rocks like those found in natural salt deposits stimulated studies of minerals crystallizing from silicate melts simulating the magmas from which igneous rocks have formed. Working at the Geo-

physical Laboratory of the Carnegie Institution of Washington, D.C., Norman L. Bowen conducted extensive phase-equilibrium studies of silicate systems, brought together in his *Evolution of the Igneous Rocks* (1928). Experimental petrology, both at the low-temperature range explored by van't Hoff and in the high ranges of temperature investigated by Bowen, continues to provide laboratory evidence for interpreting the chemical history of sedimentary and igneous rocks. Experimental petrology also provides valuable data on the stability limits of individual metamorphic minerals and of the reactions between different minerals in a wide variety of chemical systems. These experiments are carried out at elevated temperatures and pressures that simulate those operating in different levels of the Earth's crust. Thus the metamorphic petrologist today can compare the minerals and mineral assemblages found in natural rocks with comparable examples produced in the laboratory, the pressure–temperature limits of which have been well defined by experimental petrology.

Another branch of experimental science relates to the deformation of rocks. In 1906 the American physicist P.W. Bridgman developed a technique for subjecting rock samples to high pressures similar to those deep in the Earth. Studies of the behaviour of rocks in the laboratory have shown that their strength increases with confining pressure but decreases with rise in temperature. Down to depths of a few kilometres the strength of rocks would be expected to increase. At greater depths the temperature effect should become dominant, and response to stress should result in flow rather than fracture of rocks. In 1959 two American geologists, Marion King Hubbert and William W. Rubey, demonstrated that fluids in the pores of rock may reduce internal friction and permit gliding over nearly horizontal planes of the large overthrust blocks associated with folded mountains. More recently the Norwegian petrologist Hans Ramberg performed many experiments with a large centrifuge that produced a negative gravity effect and thus was able to create structures simulating salt domes, which rise because of the relatively low density of the salt in comparison with that of surrounding rocks. With all these deformation experiments, it is necessary to scale down as precisely as possible variables such as the time and velocity of the experiment and the viscosity and temperature of the material from the natural to the laboratory conditions.

Simulation of salt domes

Crystallography. In the 19th century crystallographers were only able to study the external form of minerals, and it was not until 1895 when the German physicist Wilhelm Conrad Röntgen discovered X rays that it became possible to consider their internal structure. In 1912 another German physicist, Max von Laue, realized that X rays were scattered and deflected at regular angles when they passed through a copper sulfate crystal, and so he produced the first X-ray diffraction pattern on a photographic film. A year later William Bragg of Britain and his son Lawrence perceived that such a pattern reflects the layers of atoms in the crystal structure, and they succeeded in determining for the first time the atomic crystal structure of the mineral halite (sodium chloride). These discoveries had a long-lasting influence on crystallography because they led to the development of the X-ray powder diffractometer, which is now widely used to identify minerals and to ascertain their crystal structure.

The chemical analysis of rocks and minerals. The successive stages in the plate-tectonic cycle (see below) produce igneous rocks that have geochemical patterns distinctive for each stage. Consequently, the igneous petrologist is able to use both the major and trace element abundances of rocks to define the possible tectonic environment in which they formed. The metamorphic petrologist can use the bulk composition of a recrystallized rock to define the composition of the original rock, assuming that there has been no change in composition during the metamorphic process. Advanced analytic geochemical equipment now make these studies possible.

Micropaleontology. Microscopic fossils, such as ostracods, foraminifera, and pollen grains, are common in sediments of the Mesozoic and Cenozoic eras (from about 225,000,000 years ago to the present). Because the rock chips brought up in oil wells are so small, a high-resolution instrument known as a scanning electron microscope had to be developed to study the microfossils. The classification of microfossils of organisms that lived within relatively short time spans has enabled Mesozoic-Cenozoic sediments to be subdivided in remarkable detail. This technique also has had a major impact on the study of Precambrian life (*i.e.*, organisms that existed more than 570,000,000 years ago). Carbonaceous spheroids and filaments about 7–10 millimetres (0.3–0.4 inch) long are recorded in 3,000,000,000-year-old sediments in the Pilbara region of northwestern Western Australia and in the lower Onverwacht Series of the Barberton belt in South Africa; these are the oldest reliable records of life on Earth.

Seismology and the structure of the Earth. Earthquake study was institutionalized in 1880 with the formation of the Seismological Society of Japan under the leadership of the English geologist John Milne. Milne and his associates invented the first accurate seismographs, including the instrument later known as the Milne seismograph. Seismology has revealed much about the structure of the Earth's core, mantle, and crust. The English seismologist Richard Dixon Oldham's studies of earthquake records in 1906 led to the discovery of the Earth's core. From studies of the Croatian quake of Oct. 8, 1909, the geophysicist Andrija Mohorovičić discovered the discontinuity (often called the Moho) that separates the crust from the underlying mantle.

Discovery of the Earth's core and of the Moho

Today there are more than 1,000 seismograph stations around the world, and their data are used to compile seismicity maps. These maps show that earthquake epicentres are aligned in narrow, continuous belts along the boundaries of lithospheric plates (see below). The earthquake foci outline the mid-oceanic ridges in the Atlantic, Pacific, and Indian oceans where the plates separate, while around the margins of the Pacific where the plates converge, they lie in a dipping plane, or Benioff zone, that defines the position of the subducting plate boundary to depths of about 700 kilometres.

Since 1950, additional information on the crust has been obtained from the analysis of artificial tremors produced by chemical explosions. These studies have shown that the Moho is present under all continents at an average depth of 35 kilometres and that the crust above it thickens under young mountain ranges to depths of 70 kilometres in the Andes and the Himalayas. In such investigations the reflections of the seismic waves generated from a series of "shot" points are also recorded, and this makes it possible to construct a profile of the subsurface structure. This is seismic reflection profiling, the main method of exploration used by the petroleum industry. During the late 1970s, a new technique for generating seismic waves was invented: thumping and vibrating the surface of the ground with a gas-propelled piston from a large truck.

The theory of plate tectonics. Plate tectonics has revolutionized virtually every discipline of the Earth sciences since the late 1960s and early 1970s. It has served as a unifying model or paradigm for explaining geologic phenomena that were formerly considered in unrelated fashion. Plate tectonics describes seismic activity, volcanism, mountain building, and various other Earth processes in terms of the structure and mechanical behaviour of a small number of enormous rigid plates thought to constitute the outer part of the planet (*i.e.*, the lithosphere). This all-encompassing theory grew out of observations and ideas about continental drift and seafloor spreading.

Plate tectonics as a unifying model

In 1912 the German meteorologist Alfred Wegener proposed that throughout most of geologic time there was only one continental mass, which he named Pangaea. At some time during the Mesozoic Era, Pangaea fragmented and the parts began to drift apart. Westward drift of the Americas opened the Atlantic Ocean, and the Indian block drifted across the Equator to join with Asia. In 1937 the South African Alexander Du Toit modified Wegener's hypothesis by suggesting the existence of two primordial continents: Laurasia in the north and Gondwanaland in the south. Aside from the congruency of continental shelf margins across the Atlantic, proponents of continental drift have amassed impressive geologic evidence to support their views. Similarities in fossil terrestrial organisms

The notion of continental drift

in pre-Cretaceous (older than 140,000,000 years) strata of Africa and South America and in pre-Jurassic rocks (older than 200,000,000 years) of Australia, India, Madagascar, and Africa are explained if these continents were formerly connected but difficult to account for otherwise. Fitting the Americas with the continents across the Atlantic brings together similar kinds of rocks and structures. Evidence of widespread glaciation during the Upper Paleozoic is found in Antarctica, southern South America, southern Africa, India, and Australia. If these continents were formerly united around the south polar region, this glaciation becomes explicable as a unified sequence of events in time and space.

Interest in continental drift heightened during the 1950s as knowledge of the Earth's magnetic field during the geologic past developed from the studies of Stanley K. Runcorn, Patrick M.S. Blackett, and others. Ferromagnetic minerals such as magnetite acquire a permanent magnetization when they crystallize as components of igneous rock. The direction of their magnetization is the same as the direction of the Earth's magnetic field at the place and time of crystallization. Particles of magnetized minerals released from their parent igneous rocks by weathering may later realign themselves with the existing magnetic field at the time these particles are incorporated into sedimentary deposits. Studies of the remanent magnetism in suitable rocks of different ages from over the world indicate that the magnetic poles were in different places at different times. The polar wandering curves are different for the several continents, but in important instances these differences are reconciled on the assumption that continents now separated were formerly joined. The curves for Europe and North America, for example, are reconciled by the assumption that America has drifted about 30° westward relative to Europe since the Triassic Period (195,000,000 to 230,000,000 years ago).

Remanent magnetism and polar wandering

In the early 1960s a major breakthrough in understanding the way the modern Earth works came from two studies of the ocean floor. First, the American geophysicists Harry H. Hess and Robert S. Dietz suggested that new ocean crust was formed along mid-oceanic ridges between separating continents; and second, Drummond H. Matthews and Frederick J. Vine of Britain proposed that the new oceanic crust acted like a magnetic tape recorder insofar as magnetic anomaly strips parallel to the ridge had been magnetized alternately in normal and reversed order, reflecting the changes in polarity of the Earth's magnetic field. This theory of seafloor spreading then needed testing, and the opportunity arose from major advances in deep-water drilling technology. The Joint Oceanographic Institutions Deep Earth Sampling (JOIDES) project began in 1969, continued with the Deep Sea Drilling Project (DSDP), and, since 1976, with the International Phase of Ocean Drilling (IPOD) project. These projects have produced more than 500 boreholes in the floor of the world's oceans, and the results have been as outstanding as the plate-tectonic theory itself. They confirm that the oceanic crust is everywhere younger than about 200,000,000 years and that the stratigraphic age determined by micropaleontology of the overlying oceanic sediments is close to the age of the oceanic crust calculated from the magnetic anomalies.

Theory of seafloor spreading

The plate-tectonic theory, which embraces both continental drift and seafloor spreading, was formulated in the mid-1960s by the Canadian geologist J. Tuzo Wilson, who described the network of mid-oceanic ridges, transform faults, and subduction zones as boundaries separating an evolving mosaic of enormous plates, and who proposed the idea of the opening and closing of oceans and eventual production of an orogenic belt by the collision of two continents.

Up to this point, no one had considered in any detail the implications of the plate-tectonic theory for the evolution of continental orogenic belts; most thought had been devoted to the oceans. In 1969 John Dewey of the University of Cambridge outlined an analysis of the Caledonian-Appalachian orogenic belts in terms of a complete plate-tectonic cycle of events, and this provided a model for the interpretation of other pre-Mesozoic (Paleozoic and Precambrian) belts. For a detailed discussion of plate-tectonic theory and its far-reaching effects, see PLATE TECTONICS.

Hydrologic sciences. *Water resources and seawater chemistry.* Quantitative studies of the distribution of water have revealed that an astonishingly small part of the Earth's water is contained in lakes and rivers. Ninety-seven percent of all the water is in the oceans; and, of the fresh water constituting the remainder, three-fourths is locked up in glacial ice and most of the rest is in the ground. Approximate figures are also now available for the amounts of water involved in the different stages of the hydrologic cycle. Of the 859 millimetres of annual global precipitation, 23 percent falls on the lands; but only about a third of the precipitation on the lands runs directly back to the sea, the remainder being recycled through the atmosphere by evaporation and transpiration. Subsurface groundwater accumulates by infiltration of rainwater into soil and bedrock. Some may run off into rivers and lakes, and some may reemerge as springs or aquifers. Advanced techniques are used extensively in groundwater studies nowadays. The rate of groundwater flow, for example, can be calculated from the breakdown of radioactive carbon-14 by measuring the time it takes for rainwater to pass through the ground, while numerical modeling is used to study heat and mass transfer in groundwater. High-precision equipment is used for measuring down-hole temperature, pressure, flow rate, and water level. Groundwater hydrology is important in studies of fractured reservoirs, subsidence resulting from fluid withdrawal, geothermal resource exploration, radioactive waste disposal, and aquifer thermal-energy storage.

Chemical analyses of trace elements and isotopes of seawater are conducted as part of the Geochemical Ocean Sections (Geosecs) program. Of the 92 naturally occurring elements, nearly 80 have been detected in seawater or in the organisms that inhabit it, and it is thought to be only a matter of time until traces of the others are detected. Contrary to the idea widely circulated in the older literature of oceanography, that the relative proportions of the oceans' dissolved constituents are constant, investigations since 1962 have revealed statistically significant variations in the ratios of calcium and strontium to chlorinity. The role of organisms as influences on the composition of seawater has become better understood with advances in marine biology. It is now known that plants and animals may collect certain elements to concentrations as much as 100,000 times their normal amounts in seawater. Abnormally high concentrations of beryllium, scandium, chromium, and iodine have been found in algae; of copper and arsenic in both the soft and skeletal parts of invertebrate animals; and of zirconium and cerium in plankton.

Desalinization, tidal power, and minerals from the sea. For ages a source of food and common salt, the sea is increasingly becoming a source of water, chemicals, and energy. In 1967 Key West, Fla., became the first U.S. city to be supplied solely by water from the sea, drawing its supplies from a plant that produces more than 2,000,000 gallons of refined water daily. Magnesia was extracted from the Mediterranean in the late 19th century; at present nearly all the magnesium metal used in the United States is mined from the sea at Freeport, Texas. Many ambitious schemes for using tidal power have been devised, but the first major hydrographic project of this kind was not completed until 1967, when a dam and electrical generating equipment were installed across the Rance River in Brittany. The seafloor and the strata below the continental shelves are also sources of mineral wealth. Concretions of manganese oxide, evidently formed in the process of subaqueous weathering of volcanic rocks, have been found in dense concentrations with a total abundance of 10^{11} tons. In addition to the manganese, these concretions contain copper, nickel, cobalt, zinc, and molybdenum. To date, oil and gas have been the most valuable products to be produced from beneath the sea.

Economic potential of the seafloor

Ocean bathymetry. Modern bathymetric charts show that about 20 percent of the surfaces of the continents are submerged to form continental shelves. Altogether the shelves form an area about the size of Africa. Continental slopes, which slant down from the outer edges of the

shelves to the abyssal plains of the seafloor, are nearly everywhere furrowed by submarine canyons. The depths to which these canyons have been cut below sea level seem to rule out the possibility that they are drowned valleys cut by ordinary streams. More likely the canyons were eroded by turbidity currents, dense mixtures of mud and water that originate as mud slides in the heads of the canyons and pour down their bottoms.

Profiling of the Pacific Basin prior to and during World War II resulted in the discovery of hundreds of isolated eminences rising 1,000 or more metres above the floor. Of particular interest were seamounts in the shape of truncated cones, whose flat tops rise to between 1.6 kilometres and a few hundred metres below the surface. Harry H. Hess interpreted the flat-topped seamounts (guyots) as volcanic mountains planed off by action of waves before they subsided to their present depths. Subsequent drilling in guyots west of Hawaii confirmed this view; samples of rocks from the tops contained fossils of Cretaceous age representing reef-building organisms of the kind that inhabit shallow water.

Ocean circulation, currents, and waves. Early in the century Vilhelm Bjerknes, a Norwegian meteorologist, and V. Walfrid Ekman, a Swedish physical oceanographer, investigated the dynamics of ocean circulation and developed theoretical principles that have influenced subsequent studies of currents in the sea. Bjerknes showed that very small forces resulting from pressure differences caused by nonuniform density of seawater can initiate and maintain fluid motion. Ekman analyzed the influence of winds and the Earth's rotation on currents. He theorized that in a homogeneous medium the frictional effects of winds blowing across the surface would cause movement of successively lower layers of water, the deeper the currents so produced the less their velocity and the greater their deflection by the Coriolis effect (an apparent force due to the Earth's rotation that causes deflection of a moving body to the right in the Northern Hemisphere and to the left in the Southern Hemisphere), until at some critical depth an induced current would move in a direction opposite to that of the wind.

Results of many investigations suggest that the forces that drive the ocean currents originate at the interface between water and air. The direct transfer of momentum from the atmosphere to the sea is doubtless the most important driving force for currents in the upper parts of the ocean. Next in importance are differential heating, evaporation, and precipitation across the air–sea boundary, altering the density of seawater and thus initiating movement of water masses with different densities. Studies of the properties and motion of water at depth have shown that strong currents also exist in the deep sea and that distinct types of water travel far from their geographic sources. For example, the highly saline water of the Mediterranean that flows through the Strait of Gibraltar has been traced over a large part of the Atlantic, where it forms a deep-water stratum that is circulated far beyond that ocean in currents around Antarctica.

Countercurrents and the Gulf Stream

Improvements in devices for determining the motion of seawater in three dimensions have led to the discovery of new currents and to the disclosure of unexpected complexities in the circulation of the oceans generally. In 1951 a huge countercurrent moving eastward across the Pacific was found below depths as shallow as 20 metres, and in the following year an analogous equatorial undercurrent was discovered in the Atlantic. In 1957 a deep countercurrent was detected beneath the Gulf Stream with the aid of subsurface floats emitting acoustic signals.

Since the 1970s Earth-orbiting satellites have yielded much information on the temperature distribution and thermal energy of ocean currents such as the Gulf Stream. Chemical analyses from Geosecs makes possible the determination of circulation paths, speeds, and mixing rates of ocean currents.

Surface waves of the ocean are also exceedingly complex, at most places and times reflecting the coexistence and interferences of several independent wave systems. During World War II, interest in forecasting wave characteristics was stimulated by the need for this critical information in the planning of amphibious operations. The oceanographers H.U. Sverdrup and Walter Heinrich Munk combined theory and empirical relationships in developing a method of forecasting "significant wave height"—the average height of the highest third of the waves in a wave train. Subsequently, this method was improved to permit wave forecasters to predict optimal routes for mariners. Forecasting of the most destructive of all waves, tsunamis, or "tidal waves," caused by submarine quakes and volcanic eruptions, is another recent development. Soon after 159 persons were killed in Hawaii by the tsunami of 1946, the U.S. Coast and Geodetic Survey established a seismic seawave warning system. Using a seismic network to locate epicentres of submarine quakes, the installation predicts the arrival of tsunamis at points around the Pacific Basin often hours before the arrival of the waves.

Glacier motion and the high-latitude ice sheets. Beginning around 1948, principles and techniques in metallurgy and solid-state physics were brought to bear on the mechanics of glacial movements. Laboratory studies showed that glacial ice deforms like other crystalline solids (such as metals) at temperatures near the melting point. Continued stress produces permanent deformation. In addition to plastic deformation within a moving glacier, the glacier itself may slide over its bed by mechanisms involving pressure melting and refreezing and accelerated plastic flow around obstacles. The causes underlying changes in rate of glacial movement, in particular spectacular accelerations called surges, require further study. Surges involve massive transfer of ice from the upper to the lower parts of glaciers at rates of as much as 20 metres a day, in comparison with normal advances of a few metres a year.

As a result of numerous scientific expeditions into Greenland and Antarctica, the dimensions of the remaining great ice sheets are fairly well known from gravimetric and seismic surveys. In parts of both continents it has been determined that the base of the ice is below sea level, probably due at least in part to subsidence of the crust under the weight of the caps. In 1966 a borehole was drilled 1,390 metres to bedrock on the North Greenland ice sheet, and two years later a similar boring of 2,162 metres was cut through the Antarctic ice at Byrd Station. From the study of annual incremental layers and analyses of oxygen isotopes, the bottom layers of ice cored in Greenland were estimated to be more than 150,000 years old, compared with 100,000 years for the Antarctic core. With the advent of geochemical dating of rocks it has become evident that the Ice Age, which in the earlier part of the century was considered to have transpired during the Quaternary Period, actually began much earlier. In Antarctica, for example, potassium–argon age determinations of lava overlying glaciated surfaces and sedimentary deposits of glacial origin show that glaciers existed on this continent at least 10,000,000 years ago.

Analysis of cores from the Greenland and Antarctic ice sheets

The study of ice sheets has benefited much from data produced by advanced instruments, computers, and orbiting satellites. The shape of ice sheets can be determined by numerical modeling, their heat budget from thermodynamic calculations, and their thickness with radar techniques. Colour images from satellites show the temperature distribution across the polar regions, which can be compared with the distribution of land and sea ice.

Atmospheric sciences. *Probes, satellites, and data transmission.* Kites equipped with meteorgraphs were used as atmospheric probes in the late 1890s, and in 1907 the U.S. Weather Bureau recorded the ascent of a kite to 7,044 metres above Mt. Weather, Virginia.

In the 1920s the radio replaced the telegraph and telephone as the principal instrument for transmitting weather data. By 1936 the radio meteorgraph (radiosonde) was developed, with capabilities of sending signals on relative humidity, temperature, and barometric pressure from unmanned balloons. Experimentation with balloons up to altitudes of about 31 kilometres showed that columns of warm air may rise more than 1.6 kilometres above the Earth's surface and that the lower atmosphere is often stratified, with winds in the different layers blowing in different directions. During the 1930s airplanes began to be used for observations of the weather, and the years since

1945 have seen the development of rockets and weather satellites. TIROS (Television Infra-Red Observation Satellite), the world's first all-weather satellite, was launched in 1960, and in 1964 the Nimbus Satellite of the United States National Aeronautics and Space Administration (NASA) was rocketed into near-polar orbit.

There are two types of weather satellites: polar and geostationary. Polar satellites, like Nimbus, orbit the Earth at low altitudes of a few hundred kilometres, and, because of their progressive drift, they produce a photographic coverage of the entire Earth every 24 hours. Geostationary satellites, first sent up in 1966, are situated over the Equator at altitudes of about 35,000 kilometres and transmit data at regular intervals. Much information can be derived from the data collected by satellites. For example, wind speed and direction are measured from cloud trajectories, while temperature and moisture profiles of the atmosphere are calculated from infrared data.

Weather forecasting. Efforts at incorporating numerical data on weather into mathematical formulas that could then be used for forecasting were initiated early in the century at the Norwegian Geophysical Institute. Vilhelm Bjerknes and his associates at Bergen succeeded in devising equations relating the measurable components of weather, but their complexity precluded the rapid solutions needed for forecasting. Out of their efforts, however, came the polar front theory for the origin of cyclones and the now-familiar names of cold front, warm front, and stationary front for the leading edges of air masses (see below *Study of the horizontal structure of the atmosphere*).

Bjerknes' polar front theory of cyclones

In 1922 the British mathematician Lewis Fry Richardson demonstrated that the complex equations of the Norwegian school could be reduced to long series of simple arithmetic operations. With no more than the desk calculators and slide rules then available, however, the solution of a problem in procedure only raised a new one in manpower. In 1946 the mathematician John von Neumann and his fellow workers at the Institute for Advanced Study, in Princeton, N.J., began work on an electronic device to do the computation faster than the weather developed. Four years later the von Neumann group could claim that, given adequate data, their computer could forecast the weather as well as a weatherman. Present-day numerical weather forecasting is achieved with the help of advanced computer analysis (see below *Weather forecasting*).

Cloud physics. Studies of cloud physics have shown that the nuclei around which water condenses vary widely in their degree of concentration and areal distribution, ranging from six per cubic centimetre over the oceans to more than 4,000,000 per cubic centimetre in the polluted air of some cities. The droplets that condense on these foreign particles may be as small as 0.001 centimetre in diameter. Raindrops apparently may form directly from the coalescence of these droplets, as in the case of tropical rains, or in the temperate zones through the intermediary of ice crystals. According to the theory of Tor Bergson and Walter Findeisen, vapour freezing on ice crystals in the clouds enlarges the crystals until they fall. What finally hits the ground depends on the temperature of air below the cloud—if below freezing, snow; if above, rain.

The Van Allen radiation belts

Properties and structure of the atmosphere. Less than a year after the space age began with the launching of the Soviet Sputnik I in 1957, the U.S. satellite Explorer I was sent into orbit with a Geiger counter for measuring the intensity of cosmic radiation at different levels above the ground. At altitudes around 1,000 kilometres this instrument ceased to function due to saturation by charged particles. This and subsequent investigations showed that a zone of radiation encircles the world between about latitude 75° N and 75° S, with maximum intensities at 5,000 and 16,000 kilometres. Named after the American physicist James Van Allen, a leading investigator of this portion of the Earth's magnetosphere, these zones are responsive to events taking place on the Sun. The solar wind, a stream of atomic particles emanating from the Sun in all directions, seems to be responsible for the electrons entrapped in the Van Allen region as well as for the teardrop shape of the magnetosphere as a whole, with its tail pointing always away from the Sun.

In 1898 Teisserenc de Bort, studying variations of temperature at high altitudes with the aid of balloons, discovered that at elevations of about 11 kilometres the figure for average decrease of temperature with height (about 5.5° C per 1,000 metres of ascent) dropped and the value remained nearly constant at around −55° C. He named the atmospheric zones below and above this temperature boundary the troposphere and the stratosphere.

Discovery of the jet streams

Toward the end of World War II the B-29 Superfortress came into use as the first large aircraft to cruise regularly at 10,000 metres. Heading westward from bases in the Pacific, these planes sometimes encountered unexpected head winds that slowed their flight by as much as 300 kilometres per hour. The jet streams, as these high-altitude winds were named, have been found to encircle the Earth following wavy courses and moving from west to east at velocities ranging upward to 500 kilometres per hour. Aircraft have also proved useful in studies of the structure and dynamics of tropical hurricanes. Following the destruction wrought to the Atlantic Coast of the United States in 1955 by hurricanes Connie and Diane, a national centre was established in Florida with the missions of locating and tracking and, it is hoped, of learning how to predict the paths of hurricanes and to dissipate their energy.

Weather modification. As late as the 1890s experiments were conducted in the United States in the hope of producing rain by setting off charges of dynamite lofted by balloons or kites. No positive results were reported, however. More promising were the cloud-seeding experiments of the 1940s, in which silver iodide was released into clouds as smoke or solid carbon dioxide broadcast into clouds from airplanes. The results are still uncertain for increasing precipitation. The lessons learned from cloud seeding, however, have had other successful applications, such as the dispersal of low-level supercooled fog at airports (the first system designed for this purpose, the Turboclair fog-dissipation system, was set up in 1970 at Orly airport in Paris).

The inadvertent weather modification that has followed industrialization and the building of large cities has, however, already produced measurable changes in local climate and may someday produce effects more widespread. The introduction of some 12,000,000,000 tons of carbon dioxide into the atmosphere each year from the burning of fuels may in time raise the Earth's average temperature. Cities affect the flow of wind, warm the atmosphere over them, and send pollutants into the sky. Updrafts and an abundance of condensation nuclei may increase rainfall and winter fog and reduce sunshine and daylight.

(C.C.A./B.F.W.)

Geologic sciences

An introduction to the geochemical and geophysical sciences logically begins with mineralogy because the Earth's rocks are composed of minerals—inorganic elements or compounds that have a fixed chemical composition and that are made up of regularly aligned rows of atoms. Today, one of the principal concerns of mineralogy is the chemical analysis of the some 3,000 known minerals that are the chief constituents of the three different rock types: sedimentary (formed by diagenesis of sediments deposited by surface processes); igneous (crystallized from magmas either at depth or at the surface as lavas); and metamorphic (formed by a recrystallization process at temperatures and pressures in the Earth's crust high enough to destabilize the parent sedimentary or igneous material). Geochemistry is the study of the composition of these different types of rocks.

Scope of the geologic sciences and the principal component disciplines

During mountain building, rocks became highly deformed, and the primary objective of structural geology is to elucidate the mechanism of formation of the many types of structures (*e.g.*, folds and faults) that arise from such deformation. The allied field of geophysics has several subdisciplines, which make use of different instrumental techniques. Seismology, for example, involves the exploration of the Earth's deep structure through the detailed analysis of recordings of elastic waves generated by earthquakes and man-made explosions. Earthquake seismology

has largely been responsible for defining the location of major plate boundaries and of the dip of subduction zones down to depths of about 700 kilometres at those boundaries. In other subdisciplines of geophysics, gravimetric techniques are used to determine the shape and size of underground structures; electrical methods help to locate a variety of mineral deposits that tend to be good conductors of electricity; and paleomagnetism has played the principal role in tracking the drift of continents.

Geomorphology

Geomorphology is concerned with the surface processes that create the landscapes of the world—namely, weathering and erosion. Weathering is the alteration and breakdown of rocks at the Earth's surface caused by local atmospheric conditions, while erosion is the process by which the weathering products are removed by water, ice, and wind. The combination of weathering and erosion leads to the wearing down or denudation of mountains and continents, with the erosion products being deposited in rivers, internal drainage basins, and the oceans. Erosion is thus the complement of deposition. The unconsolidated accumulated sediments are transformed by the process of diagenesis and lithification into sedimentary rocks, thereby completing a full cycle of the transfer of matter from an old continent to a young ocean and ultimately to the formation of new sedimentary rocks. Knowledge of the processes of interaction of the atmosphere and the hydrosphere with the surface rocks and soils of the Earth's crust is important for an understanding not only of the development of landscapes but also (and perhaps more importantly) of the ways in which sediments are created. This in turn helps in interpreting the mode of formation and the depositional environment of sedimentary rocks. Thus the discipline of geomorphology is fundamental to the uniformitarian approach to the Earth sciences according to which the present is the key to the past.

Geologic history provides a conceptual framework and overview of the evolution of the Earth. An early development of the subject was stratigraphy, the study of order and sequence in bedded sedimentary rocks. Stratigraphers still use the two main principles established by the late 18th-century English engineer and surveyor William Smith, regarded as the father of stratigraphy: (1) that younger beds rest upon older ones and (2) different sedimentary beds contain different and distinctive fossils, enabling beds with similar fossils to be correlated over large distances. Today, biostratigraphy uses fossils to characterize successive intervals of geologic time, but as relatively precise time markers only to the beginning of the Cambrian Period, about 540,000,000 years ago. The geologic time scale, back to the oldest rocks, some 3,900,000,000 years ago, can be quantified by isotopic dating techniques. This is the science of geochronology, which in recent years has revolutionized scientific perception of Earth history and which relies heavily on the measured parent-to-daughter ratio of radiogenic isotopes (see below).

Paleontology is the study of fossils and is concerned not only with their description and classification but also with an analysis of the evolution of the organisms involved. Simple fossil forms can be found in early Precambrian rocks as old as 3,500,000,000 years, and it is widely considered that life on Earth must have begun before the appearance of the oldest rocks. Paleontological research of the fossil record since the Cambrian Period has contributed much to the theory of evolution of life on Earth.

Several disciplines of the geologic sciences have practical benefits for society. The geologist is responsible for the discovery of minerals, oil, gas, and coal, which are the main economic resources of the Earth; for the application of knowledge of subsurface structures and geologic conditions to the building industry; and for the prevention of natural hazards or at least providing early warning of their occurrence. (For further examples, see below *Practical applications*.)

Astrogeology is important in that it contributes to understanding the development of the Earth within the solar system. The U.S. Apollo program of manned missions to the Moon, for example, provided scientists with firsthand information on lunar geology, including observations on such features as meteorite craters that are relatively rare on Earth. Unmanned space probes have yielded significant data on the surface features of many of the planets and their satellites. Since the 1970s even such distant planetary systems as those of Jupiter, Saturn, and Uranus have been explored by probes.

STUDY OF THE COMPOSITION OF THE EARTH

Mineralogy. As a discipline, mineralogy has had close historical ties with geology. Minerals as basic constituents of rocks and ore deposits are obviously an integral aspect of geology. The problems and techniques of mineralogy, however, are distinct in many respects from those of the rest of geology, with the result that mineralogy has grown to be a large, complex discipline in itself.

About 3,000 distinct mineral species are recognized, but relatively few are important in the kinds of rocks that are abundant in the outer part of the Earth. Thus a few minerals such as the feldspars, quartz, and mica are the essential ingredients in granite and its near relatives. Limestones, which are widely distributed on all continents, consist largely of only two minerals, calcite and dolomite. Many rocks have a more complex mineralogy, and in some the mineral particles are so minute that they can be identified only through specialized techniques.

Identifying minerals on the basis of physical properties

It is possible to identify an individual mineral in a specimen by examining and testing its physical properties. Determining the hardness of a mineral is the most practical way of identifying it. This can be done by using the Mohs scale of hardness, which lists 10 common minerals in their relative order of hardness: talc (softest with the scale number 1), gypsum (2), calcite (3), fluorite (4), apatite (5), orthoclase (6), quartz (7), topaz (8), corundum (9), and diamond (10). Harder minerals scratch softer ones, so that an unknown mineral can be readily positioned between minerals on the scale. Certain common objects that have been assigned hardness values roughly corresponding to those of the Mohs scale (*e.g.*, fingernail [2.5], pocketknife blade [5.5], steel file [6.5]) are usually used in conjunction with the minerals on the scale for additional reference.

Other physical properties of minerals that aid in identification are crystal form, cleavage type, fracture, streak, lustre, colour, specific gravity, and density. In addition, the refractive index of a mineral can be determined with precisely calibrated immersion oils. Some minerals have distinctive properties that help to identify them. For example, carbonate minerals effervesce with dilute acids; halite is soluble in water and has a salty taste; fluorite (and about 100 other minerals) fluoresces in ultraviolet light; and uranium-bearing minerals are radioactive.

The science of crystallography is concerned with the geometric properties and internal structure of crystals. Because minerals are generally crystalline, crystallography is an essential aspect of mineralogy. Investigators in the field may use a reflecting goniometer that measures angles between crystal faces to help determine the crystal system to which a mineral belongs. Another instrument that they frequently employ is the X-ray diffractometer, which makes use of the fact that X rays, when passing through a mineral specimen, are diffracted at regular angles. The paths of the diffracted rays are recorded on photographic film, and the positions and intensities of the resulting diffraction lines on the film provide a particular pattern. Every mineral has its own unique diffraction pattern, so crystallographers are able to determine not only the crystal structure of a mineral but the type of mineral as well.

When a complex substance such as a magma crystallizes to form igneous rock, the grains of different constituent minerals grow together and mutually interfere, with the result that they do not retain their externally recognizable crystal form. To study the minerals in such a rock, the mineralogist uses a petrographic microscope constructed for viewing thin sections of the rock, which are ground uniformly to a thickness of about 0.03 millimetre, in light polarized by two polarizing prisms in the microscope. If the rock is crystalline, its essential minerals can be determined by their peculiar optical properties as revealed in transmitted light under magnification, provided that the individual crystal grains can be distinguished. Opaque minerals, such as those with a high content of metallic

elements, require a technique employing reflected light from polished surfaces. This kind of microscopic analysis has particular application to metallic ore minerals. The polarizing microscope, however, has a lower limit to the size of grains that can be distinguished with the eye; even the best microscopes cannot resolve grains less than about 0.5 micrometre (0.0005 millimetre) in diameter. For higher magnifications the mineralogist uses an electron microscope, which produces images with diameters enlarged tens of thousands of times.

Studying the chemical composition of minerals

The methods described above are based on a study of the physical properties of minerals. Another important area of mineralogy is concerned with the chemical composition of minerals. The primary instrument used is the electron microprobe. Here, a beam of electrons is focused on a thin section of rock that has been highly polished and coated with carbon. The electron beam can be narrowed to a diameter of about one micrometre and thus can be focused on a single grain of a mineral, which can be observed with an ordinary optical-microscope system. The electrons cause the atoms in the mineral under examination to emit diagnostic X rays, the intensity and concentration of which are measured by a computer. Besides spot analysis, this method allows a mineral to be traversed for possible chemical zoning. Moreover, the concentration and relative distribution of elements such as magnesium and iron across the boundary of two coexisting minerals like garnet and pyroxene can be used with thermodynamic data to calculate the temperature and pressure at which minerals of this type crystallize.

Determining the origin of minerals

Although the major concern of mineralogy is to describe and classify the geometrical, chemical, and physical properties of minerals, it is also concerned with their origin. Physical chemistry and thermodynamics are basic tools for understanding mineral origin. Some of the observational data of mineralogy consist of the behaviour of solutions in precipitating crystalline materials under controlled conditions in the laboratory. Certain minerals can be created synthetically under conditions in which temperature and concentration of solutions are carefully monitored. Other experimental methods include study of the transformation of solids at high temperatures and pressures to yield specific minerals or assemblages of minerals. Experimental data obtained in the laboratory, coupled with chemical and physical theory, enable the conditions of origin of many naturally occurring minerals to be inferred.

Petrology. Petrology is the study of rocks, and, because most rocks are composed of minerals, petrology is strongly dependent on mineralogy. In many respects mineralogy and petrology share the same problems; for example, the physical conditions that prevail (pressure, temperature, time, and presence or absence of water) when particular minerals or mineral assemblages are formed. Although petrology is in principle concerned with rocks throughout the crust, as well as with those of the inner depths of the Earth, in practice the discipline deals mainly with those that are accessible in the outer part of the Earth's crust. Rock specimens obtained from the surface of the Moon and from other planets are also proper considerations of petrology. Fields of specialization in petrology correspond to the aforementioned three major rock types—igneous, sedimentary, and metamorphic.

Igneous petrology. Igneous petrology is concerned with the identification, classification, origin, evolution, and processes of formation and crystallization of the igneous rocks. Most of the rocks available for study come from the Earth's crust, but a few, such as eclogites, derive from the mantle. The scope of igneous petrology is very large because igneous rocks make up the bulk of the continental and oceanic crusts and of the mountain belts of the world, which range in age from early Archean to the late Tertiary Period; and they also include the high-level volcanic extrusive rocks and the plutonic rocks that formed deep within the crust. Of utmost importance to igneous petrologic research is geochemistry, which is concerned with the major- and trace-element composition of igneous rocks as well as of the magmas from which they arose. Some of the major problems within the scope of igneous petrology are: (1) the form and structure of igneous bodies, whether they be lava flows or granitic intrusions, and their relations to surrounding rocks (these are problems studied in the field); (2) the crystallization history of the minerals that make up igneous rocks (this is determined with the petrographic polarizing microscope); (3) the classification of rocks based on textural features, grain size, and the abundance and composition of constituent minerals; (4) the fractionation of parent magmas by the process of magmatic differentiation, which may give rise to an evolutionary sequence of genetically related igneous products; (5) the mechanism of generation of magmas by partial melting of the lower continental crust, suboceanic and subcontinental mantle, and subducting slabs of oceanic lithosphere; (6) the history of formation and the composition of the present oceanic crust determined on the basis of data from the International Phase of Ocean Drilling (IPOD) project; (7) the evolution of igneous rocks through geologic time; (8) the composition of the mantle from studies of the rocks and mineral chemistry of eclogites brought to the surface in kimberlite pipes; (9) the conditions of pressure and temperature at which different magmas form and at which their igneous products crystallize (determined from high-pressure experimental petrology).

Major concerns of igneous petrology

Instrumentation

The basic instrument of igneous petrology is the petrographic polarizing microscope, but the majority of instruments used today have to do with determining rock and mineral chemistry. These include the X-ray fluorescence spectrometer, equipment for neutron activation analysis, induction-coupled plasma spectrometer, electron microprobe, ionprobe, and mass spectrometer. These instruments are highly computerized and automatic and produce analyses rapidly (see below *Geochemistry*). Complex high-pressure experimental laboratories also provide vital data.

With a vast array of sophisticated instruments available, the igneous petrologist is able to answer many fundamental questions. Study of the ocean floor has been combined with investigation of ophiolite complexes, which are interpreted as slabs of ocean floor that have been thrust onto adjacent continental margins. An ophiolite provides a much deeper section through the ocean floor than is available from shallow drill cores and dredge samples from the extant ocean floor. These studies have shown that the topmost volcanic layer consists of tholeiitic basalt or mid-ocean ridge basalt that crystallized at an accreting rift or ridge in the middle of an ocean. A combination of mineral chemistry of the basalt minerals and experimental petrology of such phases allows investigators to calculate the depth and temperature of the magma chambers along the mid-ocean ridge. The depths are close to six kilometres, and the temperatures range from 1,150° C to 1,279° C. Comprehensive petrologic investigation of all the layers in an ophiolite makes it possible to determine the structure and evolution of the associated magma chamber.

In 1974 B.W. Chappell and A.J.R. White discovered two major and distinct types of granitic rock—namely, I- and S-type granitoids. The I-type has strontium-87/strontium-86 ratios lower than 0.706 and contains magnetite, sphene, and allanite but no muscovite. These rocks formed above subduction zones in island arcs and active (subducting) continental margins and were ultimately derived by partial melting of mantle and subducted oceanic lithosphere. In contrast, S-type granitoids have strontium-87/strontium-86 ratios higher than 0.706 and contain muscovite, ilmenite, and monazite. These rocks were formed by partial melting of lower continental crust. Those found in the Himalayas were formed during the Miocene Epoch some 20,000,000 years ago as a result of the penetration of India into Asia, which thickened the continental crust and then caused its partial melting.

In the island arcs and active continental margins that rim the Pacific Ocean, there are many different volcanic and plutonic rocks belonging to the calc-alkaline series. These include basalts, andesites, dacites, rhyolites, ignimbrites, tonalites, granodiorites, diorites, granites, peridotites, and gabbros. They occur typically in vast batholiths, which may reach several thousand kilometres in length and contain more than 1,000 separate granitic bodies. These calc-alkaline rocks represent the principal means of growth of the continental crust probably throughout the whole

of geologic time. Much research is devoted to them in an effort to determine the source regions of their parent magmas, the chemical evolution of the magmas, and the interrelationships of the resultant igneous rocks. Although there are still many disagreements between alternative models and different petrologists, it is generally agreed that the magmas were derived from the mantle and that there is a small chemical contribution from both the subducted oceanic slab and the continental crust through which the magmas rose. One of the major influences on the evolution of these rocks is the presence of water, which was derived originally from the dehydration of the subducted slab.

Sedimentary petrology. The field of sedimentary petrology is concerned with the description and classification of sedimentary rocks, interpretation of the processes of transportation and deposition of the sedimentary materials forming the rocks, the environment that prevailed at the time the sediments were deposited, and the alteration (compaction, cementation, and chemical and mineralogical modification) of the sediments after deposition.

Carbonate petrology and clastic petrology

There are two main branches of sedimentary petrology. One branch deals with carbonate rocks, namely limestones and dolomites, composed principally of calcium carbonate (calcite) and calcium magnesium carbonate (dolomite). Much of the complexity in classifying carbonate rocks stems partly from the fact that many limestones and dolomites have been formed, directly or indirectly, through the influence of organisms, including bacteria, lime-secreting algae, various shelled organisms (*e.g.,* mollusks and brachiopods), and by corals. In limestones and dolomites that were deposited under marine conditions, commonly in shallow warm seas, much of the material initially forming the rock consists of skeletons of lime-secreting organisms. In many examples, this skeletal material is preserved as fossils. Some of the major problems of carbonate petrology concern the physical and biological conditions of the environments in which carbonate material has been deposited, including water depth, temperature, degree of illumination by sunlight, motion by waves and currents, and the salinity and other chemical aspects of the water in which deposition occurred.

The other principal branch of sedimentary petrology is concerned with the sediments and sedimentary rocks that are essentially noncalcareous. These include sands and sandstones, clays and claystones, siltstones, conglomerates, glacial till, and varieties of sandstones, siltstones, and conglomerates (*e.g.,* the graywacke-type sandstones and siltstones). These rocks are broadly known as clastic rocks because they consist of distinct particles or clasts. Clastic petrology is concerned with classification, particularly with respect to the mineral composition of fragments or particles, as well as the shapes of particles (angular versus rounded), and the degree of homogeneity of particle sizes. Other main concerns of clastic petrology are the mode of transportation of sedimentary materials, including the transportation of clay, silt, and fine sand by wind; and the transportation of these and coarser materials through suspension in water, through traction by waves and currents in rivers, lakes, and seas, and sediment transport by ice.

Sedimentary petrology also is concerned with the small-scale structural features of sediments and sedimentary rocks. Features that can be conveniently seen in a specimen held in the hand are within the domain of sedimentary petrology. These features include the geometrical attitude of mineral grains with respect to each other, small-scale cross stratification, the shapes and interconnections of pore spaces, and the presence of fractures and veinlets.

Instruments and methods used by sedimentary petrologists include the petrographic microscope for description and classification, X-ray mineralogy for defining fabrics and small-scale structures, physical model flume experiments for studying the effects of flow as an agent of transport and the development of sedimentary structures, and mass spectrometry for calculating stable isotopes and the temperatures of deposition, cementation, and diagenesis. Wet-suit diving permits direct observation of current processes on coral reefs, and manned submersibles enable observation at depth on the ocean floor and in mid-oceanic ridges.

The plate-tectonic theory has given rise to much interest in the relationships between sedimentation and tectonics, particularly in modern plate-tectonic environments—*e.g.,* spreading-related settings (intracontinental rifts, early stages of intercontinental rifting such as the Red Sea, and late stages of intercontinental rifting such as the margins of the present Atlantic Ocean), mid-oceanic settings (ridges and transform faults), subduction-related settings (volcanic arcs, fore-arcs, back-arcs, and trenches), and continental collision-related settings (the Alpine-Himalayan belt and late orogenic basins with molasse [*i.e.,* thick association of clastic sedimentary rocks consisting chiefly of sandstones and shales]). Today, many subdisciplines of sedimentary petrology are concerned with the detailed investigation of the various sedimentary processes that occur within these plate-tectonic environments.

Metamorphic petrology. Metamorphism means change in form. In geology the term is used to refer to a solid-state recrystallization of earlier igneous, sedimentary, or metamorphic rocks. There are two main types of metamorphism: (1) contact metamorphism, in which changes induced largely by increase in temperature are localized at the contacts of igneous intrusions; and (2) regional metamorphism, in which increased pressure and temperature have caused recrystallization over extensive regions in mountain belts. Other types of metamorphism include local effects caused by deformation in fault zones, burning oil shales, and thrusted ophiolite complexes; extensive recrystallization caused by high heat flow in mid-ocean ridges; and shock metamorphism induced by high-pressure impacts of meteorites in craters on the Earth and Moon.

Types of metamorphism

Metamorphic petrology is concerned with field relations and local tectonic environments; the description and classification of metamorphic rocks in terms of their texture and chemistry, which provides information on the nature of the premetamorphic material; the study of minerals and their chemistry (the mineral assemblages and their possible reactions), which yields data on the temperatures and pressures at which the rocks recrystallized; and the study of fabrics and the relations of mineral growth to deformation stages and major structures, which provides information about the tectonic conditions under which regional metamorphic rocks formed.

A supplement to metamorphism is metasomatism: the introduction and expulsion of fluids and elements through rocks during recrystallization. When new crust is formed and metamorphosed at a mid-oceanic ridge, seawater penetrates into the crust for a few kilometres and carries much sodium with it. During formation of a contact metamorphic aureole around a granitic intrusion, hydrothermal fluids carrying elements such as iron, boron, and fluorine pass from the granite into the wall rocks. When the continental crust is thickened, its lower part may suffer dehydration and form granulites. The expelled fluids, carrying such heat-producing elements as rubidium, uranium, and thorium migrate upward into the upper crust. Much petrologic research is concerned with determining the amount and composition of fluids that have passed through rocks during these metamorphic processes.

The basic instrument used by the metamorphic petrologist is the petrographic microscope, which allows detailed study and definition of mineral types, assemblages, and reactions. If a heating/freezing stage is attached to the microscope, the temperature of formation and composition of fluid inclusions within minerals can be calculated. These inclusions are remnants of the fluids that passed through the rocks during the final stages of their recrystallization. The electron microprobe is widely used for analyzing the composition of the component minerals. The petrologist can combine the mineral chemistry with data from experimental studies and thermodynamics to calculate the pressures and temperatures at which the rocks recrystallized. By obtaining information on the isotopic age of successive metamorphic events with a mass spectrometer, pressure–temperature–time curves can be worked out. These curves chart the movement of the rocks over time as they were brought to the surface from deep within the continental crust. This technique is important for understanding metamorphic processes in two plate-tectonic

environments: (1) in subduction zones where rocks are carried down to several tens of kilometres and are then brought up to be exposed at the present surface; and (2) in thrust zones in mountain belts produced by continental collisions (*e.g.*, the Himalayas), where deep crustal rocks have been brought up to high levels by major thrusts. These examples demonstrate that metamorphic petrology plays a key role in unraveling tectonic processes in mountain belts that have passed through the plate-tectonic cycle of events.

Economic geology. The mineral commodities on which modern civilization is heavily dependent are obtained from the Earth's crust and have a prominent place in the study and practice of economic geology. In turn, economic geology consists of several principal branches that include the study of ore deposits, petroleum geology, and the geology of nonmetallic deposits (excluding petroleum), such as coal, stone, salt, gypsum, clay and sand, and other commercially valuable materials.

Branches and objectives of economic geology

The practice of economic geology is distinguished by the fact that its objectives are to aid in the exploration for and extraction of mineral resources. The objectives are therefore economic. In petroleum geology, for example, a common goal is to guide oil-well-drilling programs so that the most profitable prospects are drilled, and those that are likely to be of marginal economic value, or barren, are avoided. A similar philosophy influences the other branches of economic geology. In this sense, economic geology can be considered as an aspect of business that is devoted to economic decision making. Many deposits of economic interest, particularly those of metallic ores, are of extreme scientific interest in themselves, however, and they have warranted intensive study that has been somewhat apart from economic considerations.

The practice of economic geology provides employment for a large number of geologists. On a worldwide basis, probably more than two-thirds of those persons employed in the geologic sciences are engaged in work that touches on the economic aspects of geology. These include geologists whose main interests lie in diverse fields of the geologic sciences. For example, the petroleum industry, which collectively is the largest employer of economic geologists, attracts individuals with specialties in stratigraphy, sedimentary petrology, structural geology, paleontology, and geophysics.

Geochemistry. *Chemistry of the Earth.* Geochemistry is broadly concerned with the application of chemistry to virtually all aspects of geology. Inasmuch as the Earth is composed of the chemical elements, all geologic materials and most geologic processes can be regarded from a chemical point of view. Some of the major problems that broadly belong to geochemistry are as follows: the origin and abundance of the elements in the solar system, galaxy, and universe (cosmochemistry); the abundance of elements in the major divisions of the Earth, including the core, mantle, crust, hydrosphere, and atmosphere; the behaviour of ions in the structure of crystals; the chemical reactions in cooling magmas and the origin and evolution of deeply buried intrusive igneous rocks; the chemistry of volcanic (extrusive) igneous rocks and of phenomena closely related to volcanic activity, including hot-spring activity, emanation of volcanic gases, and origin of ore deposits formed by hot waters derived during the late stages of cooling of igneous magmas; chemical reactions involved in weathering of rocks in which earlier formed minerals decay and new minerals are created; the transportation of weathering products in solution by natural waters in the ground and in streams, lakes, and the sea; chemical changes that accompany compaction and cementation of unconsolidated sediments to form sedimentary rocks; and the progressive chemical and mineralogical changes that take place as rocks undergo metamorphism.

Kinds of geochemical problems

One of the leading general concerns of geochemistry is the continual recycling of the materials of the Earth. This process takes place in several ways: (1) It is widely believed that oceanic and continental basalts crystallized from magmas that were ultimately derived by partial melting of the Earth's mantle. Much geochemical research is devoted to the quantification of this extraction of mantle material and its contribution to crustal growth throughout geologic time in the many stages of seafloor formation and mountain building. (2) When the basalts that formed at the mid-oceanic ridge are transported across the ocean by the process of seafloor spreading, they interact with seawater, and this involves the adding of sodium to the basaltic crust and the extraction of calcium from it. (3) Geophysical data confirm the idea that the oceanic lithosphere is being consumed along the Earth's major subduction zones below the continental lithosphere—*e.g.*, along the continental margin of the Andes Mountain Ranges. This may involve pelagic sediments from the ocean floor, oceanic basalts altered by seawater exchange, gabbros, ultramafic rocks, and segments of the underlying mantle. Many geochemists are studying what happens to this subducted material and how it contributes to the growth of island arcs and Andean-type mountain belts. (4) The behaviour of dissolved materials in natural waters, under the relatively low temperatures that prevail at or near the surface of the Earth, is an integral aspect of the crustal cycle. Weathering processes supply dissolved material, including silica, calcium carbonate, and other salts, to streams. These materials then enter the oceans, where some remain in solution (*e.g.*, sodium chloride), whereas others are progressively removed to form certain sedimentary rocks, including limestone and dolomite, and, where conditions are conducive for the formation of deposits by means of evaporation, gypsum (hydrous calcium sulfate), rock salt (halite), and potash deposits may occur.

The behaviour of biological materials and their subsequent disposition are important aspects of geochemistry, generally termed organic geochemistry and biogeochemistry. Major problems of organic geochemistry include the question of the chemical environment on Earth in which life originated; the modification of the hydrosphere, and particularly the atmosphere, through the effects of life; and the incorporation of organic materials in rocks, including carbonaceous material in sedimentary rocks. The nature and chemical transformations of biological material present in deposits of coal, petroleum, and natural gas lie within the scope of organic geochemistry. Organic chemical reactions influence many geochemical processes, as, for example, rock weathering and production of soil, the solution, precipitation, and secretion of such dissolved materials as calcium carbonate, and the alteration of sediments to form sedimentary rocks. Biogeochemistry deals chiefly with the cyclic flows of individual elements and their compounds between living and nonliving systems.

Organic geochemistry and biogeochemistry

Geochemistry has applications to other subdisciplines within geology, as well as to disciplines relatively far removed from it. At one extreme, geochemistry is linked with cosmology in a number of ways. These include the study of the chemical composition of meteorites, the relative abundance of elements in the Earth, Moon, and other planets, and the ages of meteorites and of rocks of the crust of the Earth and Moon as established by radiometric means. At the other extreme, the geochemistry of traces of metals in rocks and soils and, ultimately, in the food chain has important consequences for humans and for the vast body of lesser organisms on which they are dependent and with whom they coexist. Deficiencies in traces of copper and cobalt in forage plants, for example, lead to diseases in certain grazing animals and may locally influence human health. These deficiencies are in turn related to the concentrations of these elements in rocks and the manner in which they are chemically combined within soils and rocks.

The chemical analysis of minerals is undertaken with the electron microprobe (see above). Instruments and techniques used for the chemical analysis of rocks are as follows: The X-ray fluorescent (XRF) spectrometer excites atoms with a primary X-ray beam and causes secondary (or fluorescent) X rays to be emitted. Each element produces a diagnostic X radiation, the intensity of which is measured. This intensity is proportional to the concentration of the element in the rock, and so the bulk composition can be calculated. The crushed powder of the rock is compressed into a disk or fused into a bead and loaded into the spectrometer, which analyzes it automatically under computer

Instruments and techniques for the chemical analysis of rocks

control. Analysis of most elements having concentrations of more than five parts per million is possible.

Neutron-activation analysis is based on the fact that certain elements are activated or become radiogenic when they are bombarded with a flux of neutrons formed from the radioactive decay of uranium-235 in a nuclear reactor. With the addition of the neutrons, the stable isotopes produce new unstable radionuclides, which then decay, emitting particles with diagnostic energies that can be separated and measured individually. The technique is particularly suitable for the analysis of the rare earth elements, uranium, thorium, barium, and hafnium, with a precision to less than one part per million.

The induction-coupled plasma (ICP) spectrometer can analyze over 40 elements. Here, a solution of a rock is put into a plasma, and the concentration of the elements is determined from the light emitted. This method is rapid, and the ICP spectrometer is particularly suited to analyzing large numbers of soil and stream sediment samples, as well as mineralized rocks in mineral exploration.

Isotopic geochemistry. Isotopic geochemistry has several principal roles in geology. One is concerned with the enrichment or impoverishment of certain isotopic species that results from the influence of differences in mass of molecules containing different isotopes. Measurements of the proportions of various isotopic species can be used as a form of geologic thermometer. The ratio of oxygen-16 to oxygen-18 in calcium carbonate secreted by various marine organisms from calcium carbonate in solution in seawater is influenced by the temperature of the seawater. Precise measurement of the proportions of oxygen-16 with respect to oxygen-18 in calcareous shells of some fossil marine organisms provides a means of estimating the temperatures of the seas in which they lived. The varying ocean temperatures during and between the major advances of glaciers during the ice ages have been inferred by analyzing the isotopic composition of the skeletons of floating organisms recovered as fossils in sediment on the seafloor. Other uses of isotopic analyses that involve temperature-dependent rate processes include the progressive removal of crystals from cooling igneous magmas.

Radiometric dating

Another role of isotopic geochemistry that is of great importance in geology is radiometric age dating. The ability to quantify the geologic time scale—*i.e.*, to date the events of the geologic past in terms of numbers of years—is largely a result of coupling radiometric-dating techniques with older, classical methods of establishing relative geologic ages. As explained earlier, radiometric-dating methods are based on the general principle that a particular radioactive isotope (radioactive parent or source material) incorporated in geologic material decays at a uniform rate, producing a decay product, or daughter isotope. Some radiometric "clocks" are based on the ratio of the proportion of parent to daughter isotopes, others on the proportion of parent remaining, and still others on the proportion of daughter isotopes with respect to each other. For example, uranium-238 decays ultimately to lead-206, which is one of the four naturally occurring isotopic species of lead. Minerals that contain uranium-238 when initially formed may be dated by measuring the proportions of lead-206 and uranium-238; the older the specimen, the greater the proportion of lead-206 with respect to uranium-238. The decay of potassium-40 to form argon-40 (calcium-40 is produced in this decay process as well) is also a widely used radiometric-dating tool, though there are several other parent-daughter pairs that are used in radiometric dating, including another isotope of uranium (uranium-235), which decays ultimately to form lead-207, and thorium-232, which decays to lead-208.

Uranium-238 and uranium-235 decay very slowly, although uranium-235 decays more rapidly than uranium-238. The rate of decay may be expressed in several ways. One way is by the radioactive isotope's half-life—the interval of time in which half of any given initial amount will have decayed. The half-life of uranium-238 is about 4,510,000,000 years, whereas the half-life of uranium-235 is about 713,000,000 years. Other radioactive isotopes decay at greatly differing rates, with half-lives ranging from a fraction of a second to quadrillions of years.

It is useful to combine a variety of isotopic methods to determine the complete history of a crustal rock. A samarium-147–neodymium-143 date on a granitic gneiss, for example, may be interpreted as the time of mantle–crust differentiation or crustal accretion that produced the original magmatic granite. Also, a lead-207–lead-206 date on a zircon will indicate the crystallization age of the granite. In contrast, a rubidium-87–strontium-87 date of a whole rock sample may give the time at which the rock became a closed system for migration of the strontium during the period of metamorphism that converted the granite to a granitic gneiss. When potassium-40 breaks down to argon-40, the argon continues to diffuse until the rock has cooled to about 200° C; therefore, a potassium-40–argon-40 date may be interpreted as the time when the granite cooled through a blocking temperature that stopped all argon release. This may reflect the cooling of the granite during late uplift in a young mountain belt.

Carbon-14 is a radioactive isotope of carbon (carbon-12 and carbon-13 are stable isotopes) with a half-life of 5,570 years. Carbon-14 is incorporated in all living material, for it is derived either directly or indirectly from its presence in atmospheric carbon dioxide. The moderately short half-life of carbon-14 makes it useful for dating biological materials that are more than a few hundred years old and less than 30,000 years old. It has been used to provide correlation of events within this time span, particularly those of the Pleistocene Epoch involving the Earth's most recent ice ages.

STUDY OF THE STRUCTURE OF THE EARTH

Geodesy. The scientific objective of geodesy is to determine the size and shape of the Earth. The practical role of geodesy is to provide a network of accurately surveyed points on the Earth's surface, the vertical elevations and geographic positions of which are precisely known and, in turn, may be incorporated in maps. When two geographic coordinates of a control point on the Earth's surface, its latitude and longitude, are known, as well as its elevation above sea level, the location of that point is known with an accuracy within the limits of error involved in the surveying processes. In mapping large areas, such as a whole state or country, the irregularities in the curvature of the Earth must be considered. A network of precisely surveyed control points provides a skeleton to which other surveys may be tied to provide progressively finer networks of more closely spaced points. The resulting networks of points have many uses, including anchor points or bench marks for surveys of highways and other civil features. A major use of control points is to provide reference points to which the contour lines and other features of topographic maps are tied. Most topographic maps are made using photogrammetric techniques and aerial photographs.

Establishing latitude and longitude

The Earth's figure is that of a surface called the geoid, which over the Earth is the average sea level at each location; under the continents the geoid is an imaginary continuation of sea level. The geoid is not a uniform spheroid, however, because of the existence of irregularities in the attraction of gravity from place to place on the Earth's surface. These irregularities of the geoid would bring about serious errors in the surveyed location of control points if astronomical methods, which involve use of the local horizon, were used solely in determining locations. Because of these irregularities, the reference surface used in geodesy is that of a regular mathematical surface, an ellipsoid of revolution that fits the geoid as closely as possible. This reference ellipsoid is below the geoid in some places and above it in others. Over the oceans, mean sea level defines the geoid surface, but over the land areas, the geoid is an imaginary sea-level surface.

The geoid and the spheroid

Today, perturbations in the motions of artificial satellites are used to define the global geoid and gravity pattern with a high degree of accuracy. Geodetic satellites are positioned at a height of 700–800 kilometres above the Earth. Simultaneous range observations from several laser stations fix the position of a satellite, and radar altimeters measure directly its height over the oceans. Results show that the geoid is irregular; in places its surface is up to 100 metres higher than the ideal reference ellipsoid and else-

where it is as much as 100 metres below it. The most likely explanation for this height variation is that the gravity (and density) anomalies are related to mantle convection and temperature differences at depth. An important observation that confirms this interpretation is that there is a close correlation between the gravity anomalies and the surface expression of the Earth's plate boundaries. This also strengthens the idea that the ultimate driving force of plate tectonics is a large-scale circulation of the mantle.

Geophysics. Geophysics pertains to studies of the Earth that involve the methods and principles of physics. The scope of geophysics touches on virtually all aspects of geology, ranging from considerations of the conditions in the Earth's deep interior, where temperatures of several thousands of degrees Celsius and pressures of millions of atmospheres prevail, to the Earth's exterior, including its atmosphere and hydrosphere.

The study of the Earth's interior provides a good example of the geophysicist's approach to problems. Direct observation is obviously impossible. Extensive knowledge of the Earth's interior has been derived from a variety of measurements, however, including seismic waves produced by quakes that travel through the Earth, measurements of the flow of heat from the Earth's interior into the outer crust, and by astronomical and other geologic considerations.

Geophysics may be divided into a number of overlapping branches in the following way: (1) study of the variations in the Earth's gravity field; (2) seismology, the study of the Earth's crust and interior by analysis of the transmission of elastic waves that are reflected or refracted; (3) the physics of the outer parts of the atmosphere, with particular attention to the radiation bombardment from the Sun and from outer space, including the influence of the Earth's magnetic field on radiation intercepted by the planet; (4) terrestrial electricity, which is the study of the storage and flow of electricity in the atmosphere and the solid Earth; (5) geomagnetism, the study of the source, configuration, and changes in the Earth's magnetic field and the study and interpretation of the remanent magnetism in rocks induced by the Earth's magnetic field when the rocks were formed (paleomagnetism); (6) the study of the Earth's thermal properties, including the temperature distribution of the Earth's interior and the variation in the transmission of heat from the interior to the surface; and (7) the convergence of several of the above-cited branches for the study of the large-scale structures of the Earth, such as rifts, continental margins, subduction zones, mid-oceanic ridges, thrusts, and continental sutures.

Geophysical techniques

The techniques of geophysics include measurement of the Earth's gravitational field using gravimeters on land and sea and artificial satellites in space (see above); measurement of its magnetic field with hand-held magnetometers or larger units towed behind research ships and aircraft; and seismographic measurement of subsurface structures using reflected and refracted elastic waves generated either by earthquakes or by artificial means (*e.g.*, underground nuclear explosions or ground vibrations produced with special pistons in large trucks). Other tools and techniques of geophysics are diverse. Some involve laboratory studies of rocks and other earth materials under high pressures and elevated temperatures. The transmission of elastic waves through the crust and interior of the Earth is strongly influenced by the behaviour of materials under the extreme conditions at depth; consequently, there is strong reason to attempt to simulate those conditions of elevated temperatures and pressures in the laboratory. At another extreme, data gathered by rockets and satellites yield much information about radiation flux in space and the magnetic effects of the Earth and other planetary bodies, as well as providing high precision in establishing locations in geodetic surveying, particularly over the oceans. Finally, it should be emphasized that the tools of geophysics are essentially mathematical and that most geophysical concepts are necessarily expounded mathematically.

Geophysics has major influence both as a field of pure science in which the objective is pursuit of knowledge for the sake of knowledge and as an applied science in which the objectives involve solution of problems of practical or commercial interest. Its principal commercial applications lie in the exploration for oil and natural gas and, to a lesser extent, in the search for metallic ore deposits. Geophysical methods also are used in certain geologic-engineering applications, as in determining the depth of alluvial fill that overlies bedrock, which is an important factor in the construction of highways and large buildings.

Much of the success of the plate tectonics theory has depended on the corroborative factual evidence provided by geophysical techniques. For example, seismology has demonstrated that the earthquake belts of the world demarcate the plate boundaries and that intermediate and deep seismic foci define the dip of subduction zones; the study of rock magnetism has defined the magnetic anomaly patterns of the oceans; and paleomagnetism has charted the drift of continents through geologic time. Seismic reflection profiling has revolutionized scientific ideas about the deep structure of the continents: major thrusts, such as the Wind River thrust in Wyoming and the Moine thrust in northwestern Scotland, can be seen on the profiles to extend from the surface to the Moho at about 35-kilometres depth; the Appalachian Mountains in the eastern United States must have been pushed at least 260 kilometres westward to their present position on a major thrust plane that now lies at about 15 kilometres depth; the thick crust of Tibet can be shown to consist of a stack of major thrust units; the shape and structure of continental margins against such oceans as the Atlantic and the Pacific are beautifully illustrated on the profiles; and the detailed structure of entire sedimentary basins can be studied in the search for oil reservoirs.

Structural geology. Structural geology deals with the geometric relationships of rocks and geologic features in general. The scope of structural geology is vast, extending over a scale of sizes ranging from submicroscopic lattice defects in crystals to mountain belts and plate boundaries.

Small-scale features. Structural features may be divided into two broad classes: the primary structures that were acquired in the genesis of a rock mass and the secondary structures that result from later deformation of the primary structures. Most layered rocks (sedimentary rocks, some lava flows, and pyroclastic deposits) were deposited initially as nearly horizontal layers. Rocks that were initially horizontal may be deformed later by folding and may be displaced along fractures. If displacement has occurred and the rocks on the two sides of the fracture have moved in opposite directions from each other, the fracture is termed a fault; if displacement has not occurred, the fracture is called a joint. It is clear that faults and joints are secondary structures—*i.e.*, their relative age is younger than the rocks that they intersect, but their age may be only slightly younger. Many joints in igneous rocks, for example, were produced by contraction when the rocks cooled. On the other hand, some fractures in rocks, including igneous rocks, are related to weathering processes and expansion associated with removal of overlying load. These will have been produced long after the rocks were formed. The faults and joints referred to above are brittle structures that form as discrete fractures within otherwise undeformed rocks in cool upper levels of the crust. In contrast, ductile structures result from permanent changes throughout a wide body of deformed rock at higher temperatures and pressures in deeper crustal levels. Such structures include folds and cleavage in slate belts, foliation in gneisses, and mineral lineation in metamorphic rocks.

Faults, joints, and mineral orientation

Large-scale features. Toward the other extreme are large-scale structural features, the study of which is termed tectonics or tectonophysics. These structures include mid-oceanic rifts; transform faults in the oceans; intracontinental rifts, as in the East African Rift System and on the Tibetan Highlands; wrench faults (*e.g.*, the San Andreas Fault in California) that may extend hundreds of kilometres; sedimentary basins (oil potential); thrusts, such as the Main Central thrust in the Himalayas, that measure more than 2,000 kilometres long; ophiolite complexes; passive continental margins, as around the Atlantic Ocean; active continental margins, as around the Pacific Ocean; trench systems at the mouth of subduction zones; granitic batholiths (*e.g.*, those in Sierra Nevada and Peru) that may be as long as 1,000 kilometres; complete sections of moun-

Tectonics

tain belts, such as the Andes, the Rockies, the Alps, the Himalayas, the Urals, and the Appalachians–Caledonians. Viewed as a whole, the study of these large-scale features encompasses the structural geology of plate tectonics.

Methodology. The methods of structural geology are diverse. At the smallest scale, lattice defects and dislocations in crystals can be studied in images enlarged several thousand times with transmission electron microscopes. Many structures can be examined microscopically, using the same general techniques employed in petrology, in which sections of rock mounted on glass slides are ground very thin and are then examined by transmitted light with polarizing microscopes. Of course, some structures can be studied in hand specimens, which were preferably oriented when collected in the field.

Field geology and the mapping of structural features

On a large scale, the techniques of field geology are employed. These include the preparation of geologic maps that show the areal distribution of geologic units selected for representation on the map. They also include the plotting of the orientation of such structural features as faults, joints, cleavage, small folds, and the attitude of beds with respect to three-dimensional space. A common objective is to interpret the structure at some depth below the surface. It is possible to infer with some degree of accuracy the structure beneath the surface by using information available at the surface. If geologic information from drill holes or mine openings is available, however, the configuration of rocks in the subsurface commonly may be interpreted with much greater assurance as compared with interpretations involving projection to depth based largely on information obtained at the surface. Vertical graphic sections are widely used to show the configuration of rocks beneath the surface. Balancing cross sections is an important technique in thrust belts. The lengths of individual thrust slices are added up and the total restored length is compared with the present length of the section and thus the percentage of shortening across the thrust belt can be calculated. In addition, contour maps that portray the elevation of particular layers with respect to sea level or some other datum are widely used, as are contour maps that represent thickness variations.

Strain analysis

Strain analysis is another important technique of structural geology. Strain is change in shape; for example, by measuring the elliptical shape of deformed ooliths or concretions that must originally have been circular, it is possible to make a quantitative analysis of the strain patterns in deformed sediments. Other useful kinds of specimens are deformed fossils, conglomerate pebbles, and vesicles. A long-term aim of such analysis is to determine the strain variations across entire segments of mountain belts. This information is expected to help geologists understand the mechanisms involved in the formation of such belts.

A combination of structural and geophysical methods are generally used to conduct field studies of the large-scale features mentioned above. Field work enables the mapping of the structures at the surface, and geophysical methods involving the study of seismic activity, magnetism, and gravity make possible the determination of the subsurface structures.

The processes that affect geologic structures rarely can be observed directly. The nature of the deforming forces and the manner in which the Earth's materials deform under stress can be studied experimentally and theoretically, however, thus providing insight into the forces of nature. One form of laboratory experimentation involves the deformation of small, cylindrical specimens of rocks under very high pressures. Other experimental methods include the use of scale models of folds and faults consisting of soft, layered materials, in which the objective is to simulate the behaviour of real strata that have undergone deformation on a larger scale over much longer time.

Some experiments measure the main physical variables that control rock deformation—namely, temperature, pressure, deformation rate, and the presence of fluids such as water. These variables are responsible for changing the rheology of rocks from rigid and brittle at or near the Earth's surface to weak and ductile at great depths. Thus experimental studies aim to define the conditions under which deformation occurs throughout the Earth's crust.

Volcanology. Volcanology is the science of volcanoes and deals with their structure, petrology, and origin. It is also concerned with the contribution of volcanoes to the rock structure of the Earth's crust, with their role as contributors to the atmosphere and hydrosphere and to the balance of chemical elements in the Earth's crust, and with the relationships of volcanoes to certain forms of metallic ore deposits.

Many of the problems of volcanology are closely related to those of the origin of oceans and continents. Most of the volcanoes of the world are aligned along or close to the major plate boundaries, in particular the mid-oceanic ridges and active continental margins (*e.g.*, the "ring of fire" around the Pacific Ocean). A few volcanoes occur within oceanic plates (*e.g.*, along the Hawaiian chain); these are interpreted as the tracks of plumes (ascending jets of partially molten mantle material) that formed when such a plate moved over hot spots fixed in the mantle.

One of the principal reasons for studying volcanoes and volcanic products is that the atmosphere and hydrosphere are believed to be largely derived from volcanic emanations, modified by biological processes. Much of the water present at the Earth's surface, which has aggregated mostly in the oceans but to a lesser extent in glaciers, streams, lakes, and groundwater, probably has emerged gradually from the Earth's interior by means of volcanoes, beginning very early in the Earth's history. The principal components of air—nitrogen and oxygen—probably have been derived through modification of ammonia and carbon dioxide emitted by volcanoes. Emissions of vapours and gases from volcanoes are an aspect of the degassing of the Earth's interior. Although the degassing processes that affect the Earth were probably much more vigorous when it was newly formed about 4,600,000,000 years ago, it is interesting to consider that the degassing processes are still at work. Their scale, however, is vastly reduced compared with their former intensity.

The study of volcanoes is dependent on a variety of techniques. The petrologic polarizing microscope is used for classifying lava types and for tracing their general mineralogical history. The X-ray fluorescence spectrometer provides a tool for making chemical analyses of rocks that are important for understanding the chemistry of a wide variety of volcanic products (*e.g.*, ashes, pumice, scoriae, and bombs) and of the magmas that give rise to them. Some lavas are enriched or depleted in certain isotopic ratios that can be determined with a mass spectrometer. Analyses of gases from volcanoes and of hot springs in volcanic regions provide information about the late stages of volcanic activity. These late stages are characterized by the emission of volatile materials, including sulfurous gases. Many commercially valuable ore deposits have formed through the influence of hydrothermal volcanic solutions.

Prediction of eruptions

Volcanoes may pose a serious hazard to human life and property, as borne out by the destruction wrought by the eruptions of Mount Vesuvius (AD 79), Krakatoa (1883), Mount Pelée (1902), and Mount Saint Helens (1980), to mention only a few. Because of this, much attention has been devoted to forecasting volcanic outbursts. In 1959 researchers monitored activity leading up to the eruption of Kilauea in Hawaii. Using seismographs, they detected swarms of earthquake tremors for several months prior to the eruption, noting a sharp increase in the number and intensity of small quakes shortly before the outpouring of lava. Tracking such tremors, which are generated by the upward movement of magma from the asthenosphere, has proved to be an effective means of determining the onset of eruptions and is now widely used for prediction purposes. Some volcanoes inflate when rising molten rock fills their magma chambers, and in such cases tiltmeters can be employed to detect a change in angle of the slope before eruption. Other methods of predicting violent volcanic activity involve the use of laser beams to check for changes in slope, temperature monitors, gas detectors, and instruments sensitive to variations in magnetic and gravity fields. Permanent volcano observatories have been established at some of the world's most active sites (*e.g.*, Kilauea, Mount Etna, and Mount Saint Helens) to ensure early warning.

STUDY OF SURFACE FEATURES AND PROCESSES

Geomorphology. Geomorphology is literally the study of the form or shape of the Earth, but it deals principally with the topographical features of the Earth's surface. It is concerned with the classification, description, and origin of landforms. The configuration of the Earth's surface reflects to some degree virtually all of the processes that take place at or close to the surface as well as those that occur deep in the crust. The intricate details of the shape of a mountain range, for example, result more or less directly from the processes of erosion that progressively remove material from the range. The spectrum of erosive processes includes weathering and soil-forming processes and transportation of materials by running water, wind action, and mass movement. Glacial processes have been particularly influential in many mountainous regions. These processes are destructional in the sense that they modify and gradually destroy the previous form of the range. Also important in governing the external shape of the range are the constructional processes that are responsible for uplift of the mass of rock from which the range has been sculptured. A volcanic cone, for example, may be created by the successive outpouring of lava, perhaps coupled with intermittent ejection of volcanic ash and tuff. If the cone has been built up rapidly, so that there has been relatively little time for erosive processes to modify its form, its shape is governed chiefly by the constructional processes involved in the outpouring of volcanic material. But the forces of erosion begin to modify the shape of a volcanic landform almost immediately and continue indefinitely. Thus, at no time can its shape be regarded as purely constructional or purely destructional, for its shape is necessarily a consequence of the interplay of these two major classes of processes.

Destructional and constructional geomorphic processes

Investigating the processes that influence landforms is an important aspect of geomorphology. These processes include the weathering caused by the action of solutions of atmospheric carbon dioxide and oxygen in water on exposed rocks; the activity of streams and lakes; the transport and deposition of dust and sand by wind; the movement of material through downhill creep of soil and rock and by landslides and mudflows; and shoreline processes that involve the mechanics and effects of waves and currents. Study of these different types of processes forms subdisciplines that exist more or less in their own right.

Glacial geology. Glacial geology can be regarded as a branch of geomorphology, though it is such a large area of research that it stands as a distinct subdiscipline within the geologic sciences. Glacial geology is concerned with the properties of glaciers themselves as well as with the effects of glaciers as agents of both erosion and deposition. Glaciers are accumulations of snow transformed into solid ice. Important questions of glacial geology concern the climatic controls that influence the occurrence of glaciers, the processes by which snow is transformed into ice, and the mechanism of the flow of ice within glaciers. Other important questions involve the manner in which glaciers serve as erosive agents, not only in mountainous regions but also over large regions where great continental glaciers now extend or once existed. Much of the topography of the northern part of North America and Eurasia, for example, has been strongly influenced by glaciers. In places, bedrock has been scoured of most surficial debris. Elsewhere, deposits of glacial till mantle much of the area. Other extensive deposits include unconsolidated sediments deposited in former lakes that existed temporarily as a result of dams created by glacial ice or by glacial deposits. Many presently existing lakes are of glacial origin as, for example, the Great Lakes.

Glacial features and deposits

Research in glacial geology is conducted with a variety of tools. Investigators use, for example, radar techniques to determine the thickness of glaciers. In order to calculate the progressive advance or retreat of glacial masses, they ascertain the age of organic materials associated with glacial moraines by means of isotopic analyses.

Other branches of the geologic sciences are closely linked with glacial geology. In glaciated regions the problems of hydrology and hydrogeology are strongly influenced by the presence of glacial deposits. Furthermore, the suitability of glacial deposits as sites for buildings, roads, and other man-made features is influenced by the mechanical properties of the deposits and by soils formed on them.

EARTH HISTORY

Historical geology and stratigraphy. One of the major objectives of geology is to establish the history of the Earth from its inception to the present. The most important evidence from which geologic history can be inferred is provided by the geometric relationships of rocks with respect to each other, particularly layered rocks, or strata, the relative ages of which may be determined by applying simple principles. One of the major principles of stratigraphy is that within a sequence of layers of sedimentary rock, the oldest layer is at the base and that the layers are progressively younger with ascending order in the sequence. This is termed the law of superposition and is one of the great general principles of geology. Ordinarily, beds of sedimentary rocks are deposited more or less horizontally. In some regions sedimentary strata have remained more or less horizontal long after they were deposited. Some of these sedimentary rocks were deposited in shallow seas that once extended over large areas of the present continents. In many places sedimentary rocks lie much above sea level, reflecting vertical shift of the crust relative to sea level. In regions where the rocks have been strongly deformed through folding or faulting, the original attitudes of strata may be greatly altered, and sequences of strata that were once essentially horizontal may now be steeply inclined or overturned.

The law of superposition as a guiding principle

Prior to the development of radiometric methods of dating rocks, the ages of rocks and other geologic features could not be expressed quantitatively, or as numbers of years, but instead were expressed solely in terms of relative ages, in which the age of a particular geologic feature could be expressed as relatively younger or older than other geologic features. The ages of different sequences of strata, for example, can be compared with each other in this manner, and their relative ages with respect to faults, igneous intrusions, and other features that exhibit crosscutting relationships can be established. Given such a network of relative ages, a chronology of events has been gradually established in which the relative time of origin of various geologic features is known. This is the main thread of historical geology—an ordered sequence of geologic events whose occurrence and relative ages have been inferred from evidence preserved in the rocks. In turn, the development of radiometric dating methods has permitted numerical estimates of age to be incorporated in the scale of geologic time.

The development of the mass spectrometer has provided researchers with a means of calculating quantitative ages for rocks throughout the whole of the geologic record. With the aid of various radiometric methods involving mass spectrometric analysis, researchers have found it possible to determine how long ago a particular sediment was deposited, when an igneous rock crystallized or when a metamorphic rock recrystallized, and even the time at which rocks in a mountain belt cooled or underwent uplift. Radiometric dating also helped geochronologists discover the vast span of geologic time. The radiometric dating of meteorites revealed that the Earth, like other bodies of the solar system, is about 4,600,000,000 years old and that the oldest rocks so far discovered formed roughly 3,800,000,000 years ago. It has been established that the Precambrian time occupies seven-eighths of geologic time, but the era is still poorly understood in comparison with the Phanerozoic Eon—the span of time extending from about the beginning of the Cambrian Period to the Holocene Epoch during which complex life forms are known to have existed. The success of dating Phanerozoic time with some degree of precision has depended on the interlinking of radiometric ages with biostratigraphy, which is the correlation of strata with fossils.

Importance of radiometric dating

Paleontology. The geologic time scale is based principally on the relative ages of sequences of sedimentary strata. Establishing the ages of strata within a region, as well as the ages of strata in other regions and on different continents, involves stratigraphic correlation from place to

place. Although correlation of strata over modest distances often can be accomplished by tracing particular beds from place to place, correlation over long distances and over the oceans almost invariably involves comparison of fossils. With rare exceptions, fossils occur only in sedimentary strata. Paleontology, which is the science of ancient life and deals with fossils, is mutually interdependent with stratigraphy and with historical geology. Paleontology also may be considered to be a branch of biology.

Organic evolution and index fossils

Organic evolution is the essential principle involved in the use of fossils for stratigraphic correlation. It incorporates progressive irreversible changes in the succession of organisms through time. A small proportion of types of organisms has undergone little or no apparent change over long intervals of geologic time, but most organisms have progressively changed, and earlier forms have become extinct and, in turn, have been succeeded by more modern forms. Organisms preserved as fossils that lived over a relatively short span of geologic time and that were geographically widespread are particularly useful for stratigraphic correlation. These fossils are indexes of relative geologic age and may be termed index fossils.

Fossils play another major role in geology because they serve as indicators of ancient environments. Specialists called paleoecologists seek to determine the environmental conditions under which a fossil organism lived and the physical and biological constraints on those conditions. Did the organism live in the seas, lakes, or bogs? In what type of biological community did it live? What was its food chain? In short, what ecological niche did the organism occupy? Because oil and natural gas only accumulate in restricted environments, paleoecology can offer useful information for fossil fuel exploration.

Invertebrate paleontology. One of the major branches of paleontology is invertebrate paleontology, which is principally concerned with fossil marine invertebrate animals large enough to be seen with little or no magnification. The number of invertebrate fossil forms is large and includes brachiopods, pelecypods, cephalopods, gastropods, corals and other coelenterates (*e.g.*, jellyfish), bryozoans, sponges, various arthropods (invertebrates with limbs—*e.g.*, insects), including trilobites, echinoderms, and many other forms, some of which have no living counterparts. The invertebrates that are used as index fossils generally possess hard parts, a characteristic that has fostered their preservation as fossils. The hard parts preserved include the calcareous or chitinous shells of the brachiopods, cephalopods, pelecypods, and gastropods, the jointed exoskeletons of such arthropods as the trilobites, and the calcareous skeletons of frame-building corals and bryozoans. The vast variety of organisms lacking hard parts are poorly represented in the geologic record; however, they have sometimes been found to occur as impressions or carbonized films in finely laminated sediments.

Vertebrate paleontology. Vertebrate paleontology is concerned with fossils of the vertebrates: fish, amphibians, reptiles, birds, and mammals. Although vertebrate paleontology has close ties with stratigraphy, vertebrate fossils usually have not been extensively used as index fossils for stratigraphic correlation, vertebrates generally being much larger than invertebrate fossils and consequently rarer. Fossil mammals, however, have been widely used as index fossils for correlating certain nonmarine strata deposited during the Tertiary Period (from 66,400,000 to 1,600,000 years ago).

Micropaleontology. Micropaleontology involves the study of organisms so small that they can be observed only with the aid of a microscope. The size range of microscopic fossils, however, is immense. In most cases, the term micropaleontology connotes that aspect of paleontology devoted to the Ostracoda, a subclass of crustaceans that are generally less than one millimetre in length; Radiolaria, marine (typically planktonic) protozoans whose remains are common in deep ocean-floor sediments; and Foraminifera, marine protozoans that range in size from about 10 centimetres to a fraction of a millimetre.

Sizes of microfossils

Generally speaking, micropaleontology involves successive ranges of sizes of microscopic fossils down to organisms that must be magnified hundreds of times or more for viewing. The study of ultrasmall fossils is perhaps the fastest growing segment of contemporary paleontology and is dependent on modern laboratory instruments, including electron microscopes. It is an important aspect of oil and natural-gas exploration. Microfossils, which are flushed up boreholes in the drilling mud, can be analyzed to determine the depositional environment of the underlying sedimentary rocks and their age. This information enables geologists to evaluate the reservoir potential of the rock (*i.e.*, its capacity for holding gas or oil) and its depth. Ostracods and foraminiferans occur in such abundance and in so many varieties and shapes that they provide the basis for a detailed classification and time division of Mesozoic and Cenozoic sediments in which oil may occur.

Filamentous and spheroidal microfossils are important in many Precambrian sediments such as chert. They occur in rocks as old as 3,500,000,000 years and are thus an important testimony of early life on Earth.

Paleobotany. Paleobotany is the study of fossil plants. The oldest widely occurring fossils are various forms of calcareous algae that apparently lived in shallow seas, although some may have lived in freshwater. Their variety is so profuse that their study forms an important branch of paleobotany. Other forms of fossil plants consist of land plants or of plants that lived in swamp forests, standing in water that was fresh or may have been brackish, such as the coal-forming swamps of the Late Carboniferous Period (from 320,000,000 to 286,000,000 years ago).

Palynology. Palynology deals with plant spores and pollen that are both ancient and modern and is a branch of paleobotany. It plays an important role in the investigation of ancient climates, particularly through studies of deposits formed during glacial and interglacial stages. Study of a sequence of spore- or pollen-bearing beds may reveal successive climatic changes, as indicated by changes in types of spores and pollen derived from different vegetative complexes. Spores and pollen are borne by the wind and spread over large areas. Furthermore, they tend to be resistant to decay and thus may be preserved in sediments under adverse conditions.

Astrogeology. Astrogeology is concerned with the geology of the solid bodies in the solar system, such as the asteroids and the planets and their moons. Research in this field helps scientists to better understand the evolution of the Earth in comparison with that of its neighbours in the solar system. This subject was once the domain of astronomers, but the advent of spacecraft has made it accessible to geologists, geophysicists, and geochemists. The success of this field of study has depended largely on the development of advanced instrumentation.

The U.S. Apollo program enabled humans to land on the Moon several times since 1969. Rocks were collected, geophysical experiments were set up on the lunar surface, and geophysical measurements were made from spacecraft. The Soyuz program of the Soviet Union also collected much geophysical data from orbiting spacecraft. The mineralogy, petrology, geochemistry, and geochronology of lunar rocks were studied in detail, and this research made it possible to work out the geochemical evolution of the Moon. The various manned and unmanned missions to the Moon resulted in many other accomplishments: for example, a lunar stratigraphy was constructed; geologic maps at a scale of 1:1,000,000 were prepared; the structure of the maria, rilles, and craters was studied; gravity profiles across the dense, lava-filled maria were produced; the distribution of heat-producing radioactive elements, such as uranium and thorium, was mapped with gamma-ray spectrometers; the Moon's internal structure was determined on the basis of seismographic records of moonquakes; the heat flow from the interior was measured; and the day and night temperatures at the surface were recorded.

Studies of the Moon

From the late 1960s to the early 1990s, unmanned spacecraft were sent to the neighbouring planets by American and Soviet scientists. Several of these probes were soft-landed on Mars and Venus. Soil scoops from the Martian surface have been chemically analyzed by an on-board X-ray fluorescence spectrometer. The radioactivity of the surface materials of both Mars and Venus have been studied with a gamma-ray detector, the isotopic composition

Exploration of the inner planets

of their atmospheres analyzed with a mass spectrometer, and their magnetic fields measured. Relief and geologic maps of Mars have been made from high-resolution photographs and topographical maps of Venus compiled from radar data transmitted by orbiting spacecraft. Photographs of Mars and Mercury show that their surfaces are studded with many meteorite craters similar to those on the Moon. Detailed studies have been made of the craters, volcanic landforms, lava flows, and rift valleys on Mars, and a simplified geologic-thermal history has been constructed for the planet.

By the mid-1980s, the United States had sent interplanetary probes past Jupiter, Saturn, and Uranus. The craft transmitted data and high-resolution photographs of these outer planetary systems, including their rings and satellites.

This research has given increased impetus to the study of tektites, meteorites, and meteorite craters on Earth. The mineralogy, geochemistry, and isotopic age of meteorites and tektites have been studied in detail. Meteorites are very old and probably originated in the asteroid belt between Mars and Jupiter, while tektites are very young and most likely formed from material ejected from terrestrial meteorite craters. Many comparative studies have been made of the development and shapes of meteorite craters on Earth, the Moon, Mars, and Mercury. Space exploration has given birth to a new science—the geology of the solar system. The Earth can now be understood within the framework of planetary evolution.

PRACTICAL APPLICATIONS

Exploration for energy and mineral sources. Over the past century, industries have developed rapidly, populations have grown dramatically, and standards of living have improved, resulting in an ever-growing demand for energy and mineral resources. Geologists and geophysicists have led the exploration for fossil fuels (coal, oil, natural gas, etc.) and concentrations of geothermal energy, for which applications have grown in recent years. They also have played a major role in locating deposits of commercially valuable minerals.

Coal. The Industrial Revolution of the late 18th and 19th centuries was fueled by coal. Though it has been supplanted by oil and natural gas as the primary source of energy in most modern industrial nations, coal nonetheless remains an important fuel.

The U.S. Geological Survey has estimated that only about 2 percent of the world's minable coal has so far been exploited; known reserves should last for at least 300 to 400 years. Moreover, new coal basins continue to be found, as, for example, the lignite basin discovered in the mid-1980s in Rājasthān in northwestern India.

Locating coal-bearing areas

Coal-exploration geologists have found that coal was formed in two different tectonic settings: (1) swampy marine deltas on stable continental margins, and (2) swampy freshwater lakes in graben (long, narrow troughs between two parallel normal faults) on continental crust. Knowing this and the types of sedimentary rock formations that commonly include coal, geologists can quite readily locate coal-bearing areas. Their main concern, therefore, is the quality of the coal and the thickness of the coal bed or seam. (A coal seam must be at least 61 centimetres thick to be mined profitably.) Such information can be derived from samples obtained by drilling into the rock formation in which the coal occurs.

Oil and natural gas. During the last half of the 20th century, the consumption of petroleum products increased sharply. This has led to a depletion of many existing oil fields, notably in the United States, and intensive efforts to find new deposits.

Crude oil and natural gas in commercial quantities are generally found in sedimentary rocks along rifted continental margins and in intracontinental basins. Such environments exhibit the particular combination of geologic conditions and rock types and structures conducive to the formation and accumulation of liquid and gaseous hydrocarbons. They contain suitable source rocks (organically rich sedimentary rocks such as black shale), reservoir rocks (those of high porosity and permeability capable of holding the oil and gas that migrate into them), and overlying impermeable rocks that prevent the further upward movement of the fluids. These so-called cap rocks form petroleum traps, which may be either structural or stratigraphic depending on whether they were produced by crustal deformation or original sedimentation patterns.

Techniques of petroleum exploration

Petroleum geologists concentrate their search for oil deposits in such geologic settings, mapping both the surface and subsurface features of a promising area in great detail. Geologic surface maps show subcropping sedimentary rocks and features associated with structural traps such as ridges formed by anticlines during the early stages of folding and lineations produced by fault ruptures. Maps of this kind may be based on direct observation or may be constructed with photographs taken from aircraft and Earth-orbiting satellites, particularly of terrain in remote areas. Subsurface maps reveal possible hidden underground structures and lateral variations in sedimentary rock bodies that might form a petroleum trap. The presence of such features can be detected by various means, including gravity measurements, seismic methods, and the analysis of borehole samples from exploratory drilling. (For a description of these techniques, see EXPLORATION: *Exploration of the Earth's surface and interior.*)

Another method used by petroleum geologists in exploratory areas involves the sampling of surface waters from swamps, streams, or lakes. The water samples are analyzed for traces of hydrocarbons, the presence of which would indicate seepage from a subsurface petroleum trap. This geochemical technique, along with seismic profiling, is often used to search for offshore petroleum accumulations.

Once an oil deposit has actually been located and well drilling is under way, petroleum geologists can determine from core samples the depth and thickness of the reservoir rock as well as its porosity and permeability. Such information enables them to estimate the quantity of the oil present and the ease with which it can be recovered.

Oil shales and tar sands as possible alternative energy resources

Although only about 15 percent of the world's oil has been exploited, petroleum geologists estimate that at the present rate of demand the supply of recoverable oil will last no more than 100 years. Owing to this rapid depletion of conventional oil sources, economic geologists have explored oil shales and tar sands as potential supplementary petroleum resources. Extracting oil from these substances is, however, very expensive and involves possible environmental problems. But both are abundant, and advances in recovery technology may yet make them attractive alternative energy resources.

Geothermal energy. Another alternate energy resource is the heat from the Earth's interior. The surface expression of this energy is manifested in volcanoes, fumaroles, steam geysers, hot springs, and boiling mud pools. Global heat-flow maps constructed from geophysical data show that the zones of highest heat flow occur along the active plate boundaries. There is, in effect, a close association between geothermal energy sources and volcanically active regions.

A variety of applications have been developed for geothermal energy. For example, public buildings, residential dwellings, and greenhouses in such areas as Reykjavík, Ice., are heated with water pumped from hot springs and geothermal wells. Hot water from such sources also is used for heating soil to increase crop production (*e.g.*, in Oregon) and for seasoning lumber (*e.g.*, in parts of New Zealand). The most significant application of geothermal energy, however, is the generation of electricity. The first geothermal power station began operation in Larderello, Italy, in the early 1900s. Since then similar facilities have been built in various countries, including Iceland, Japan, Mexico, New Zealand, Turkey, and the United States. In most cases turbines are driven with steam separated from superheated water tapped from underground geothermal reservoirs and geysers.

Mineral deposits. As was mentioned above, the distribution of commercially significant mineral deposits, the economic factors associated with their recovery, and the estimates of available reserves constitute the basic concerns of economic geologists. Because continued industrial development is heavily dependent on mineral resources, their work is crucial to modern society.

Mineral deposits in particular types of plate-tectonic environments

It has long been known that certain periods of Earth history were especially favourable for the concentration of specific types of minerals. Copper, zinc, nickel, and gold are important in Archean rocks; magnetite and hematite are concentrated in early Proterozoic banded-iron formations; and there are economic Proterozoic uranium reserves in conglomerates. These mineral deposits and a variety of others that developed throughout the Phanerozoic Eon can be related to specific types of plate-tectonic environments. Among the latter are copper, lead, and zinc in intracontinental rifts. An interesting discovery has been the remarkable concentrations of gold, iron, zinc, and copper in brine pools and sulfide-rich muds in the Red Sea and in the Salton Sea in southern California. In many countries copper, nickel, and chromium deposits occur in ophiolite complexes obducted onto the continents from the ocean floor; porphyry copper and molybdenum deposits are found in association with granodioritic intrusions; and tungsten and tin deposits occur in many granites. The correlation of these associations and distributions with periods of Earth history, on the one hand, and plate-tectonic settings, on the other, have enabled regional metallogenetic provinces to be defined, which have proved helpful in the search for ore deposits.

During the 20th century the exploitation of mineral deposits has been so intense that serious depletion of many resources is predicted. Mercury reserves, for example, are particularly low. To deal with this problem, it has become necessary to mine deposits having smaller and smaller workable grades, a trend well illustrated by the copper mining industry, which now extracts copper from rocks with grades as low as 0.2 percent.

Investigators have discovered a major potential metallic source on the deep ocean floor, where there are large concentrations of manganese-rich nodules along with minor amounts of copper, nickel, and cobalt. Such concentrations are especially abundant in three sections of the Pacific Ocean—the area near Hawaii, that northeast of New Zealand, and that west of Central America.

Earthquake prediction and control. No natural event is as destructive over so large an area in so short a time as an earthquake. Throughout the centuries earthquakes have been responsible not only for millions of deaths but also for tremendous damage to property and the natural landscape. If major earthquakes could be predicted, it would be possible to evacuate population centres and take other measures that could minimize the loss of life and perhaps reduce damage to property as well. For this reason earthquake prediction has become a major concern of seismologists in the United States, the Soviet Union, Japan, and China.

World seismicity patterns show that earthquakes tend to occur along active plate boundaries where there is subduction (Japan) or strike-slip motion (California) and along strike-slip faults (as in China, where they are the result of the northward migration of India into Asia). Investigators agree that much more has to be learned about the physical properties of rocks in fault zones before they are able to make use of changes in these properties to predict earthquakes. Recent research has suggested that rocks may become strained shortly before an earthquake and affect such observable properties of the Earth's crust as seismic wave velocity and radon concentration. Leveling surveys and tiltmeter measurements have revealed that deformation in the fault zone just prior to an earthquake may cause changes in ground level and, in certain cases, variations in groundwater level. Also, some investigators have reported changes in the electric resistivity and remanent magnetization of rocks as precursory phenomena.

Possible precursory phenomena

Since the San Francisco earthquake of 1906, seismic activity along the nearby San Andreas Fault has been closely monitored. It has been observed that numerous semicontinuous microearthquakes have occurred along some sections of the fault. These small quakes seem to release built-up strain and thus prevent large earthquakes. By contrast, intervening sections of the fault are apparently locked and thus manifest no microshocks. Consequently, seismic strain accumulating in these locked sections is expected to be released one day in a major quake.

Seismological research includes the study of earthquakes caused by human activities, such as impounding water behind high dams, injecting fluids into deep wells, excavating mines, and detonating underground nuclear explosions. In all of these cases except for deep mining, seismologists have found that the induction mechanism most likely involves the release of elastic strain, just as with earthquakes of tectonic origin. Studies of artificially induced quakes suggest that one possible method of controlling natural earthquakes is to inject fluids into fault zones so as to release strain energy.

Artificially induced quakes

Seismologists have done much to explain the characteristics of ground motions recorded in earthquakes. Such information is required to predict ground motions in future earthquakes, thereby enabling engineers to design earthquake-resistant structures. The largest percentage of the deaths and property damage that result from an earthquake is attributable to the collapse of buildings, bridges, and other man-made structures during the violent shaking of the ground. An effective way of reducing the destructiveness of earthquakes, therefore, is to build structures capable of withstanding intense ground motions.

Other areas of application. The fields of engineering, environmental, and urban geology are broadly concerned with applying the findings of geologic studies to construction engineering and to problems of land use. The location of a bridge, for example, involves geologic considerations in selecting sites for the supporting piers. The strength of geologic materials such as rock or compacted clay that occur at the sites of the piers should be adequate to support the load placed on them. Engineering geology is concerned with the engineering properties of geologic materials, including their strength, permeability, and compactability, and with the influence of these properties on the selection of locations for buildings, roads and railroads, bridges, dams, and other major civil features.

Urban and environmental geology

Urban geology involves the application of engineering geology and other fields of geology to environmental problems in urban areas. Environmental geology is generally concerned with those aspects of geology that touch on the human environment. Environmental and urban geology deal in large measure with those aspects of geology that directly influence land use. These include the stability of sites for buildings and other civil features, sources of water supply, contamination of waters by sewage and chemical pollutants, selection of sites for burial of refuse so as to minimize pollution by seepage, and locating the source of geologic building materials, including sand, gravel, and crushed rock. (J.W.Ha./B.F.W.)

Hydrologic sciences

Scope of the hydrologic sciences

The hydrologic sciences deal with the study of the waters of the Earth. In its widest sense hydrology encompasses the study of the occurrence, the movement, and the physical and chemical characteristics of water in all its forms within the Earth's hydrosphere. In practice hydrologists usually restrict their studies to waters close to the land surface of the Earth. Water in the atmosphere is usually studied as part of meteorology (see below *Atmospheric sciences*). Water in the oceans and seas is studied within the science of oceanography; water in lakes and inland seas within limnology; and ice on the land surface within glaciology. Clearly there is some overlap between these major scientific disciplines; both hydrologists and meteorologists, for example, have contributed to the study of water movement in the lower boundary layers of the atmosphere. All are linked by the fundamental concept of the hydrologic cycle, according to which the waters of the sea are evaporated, are subsequently condensed within the atmosphere, fall to the Earth as precipitation, and finally flow in the rivers back to the sea.

Water is the most abundant substance on Earth and is the principal constituent of all living things. Water in the atmosphere plays a major role in maintaining a habitable environment for human life. The occurrence of surface waters has played a significant role in the rise and decline of the major civilizations in world history. In many societies the importance of water to humankind is reflected in

the legal and political structures. At the present time rising populations and improving living standards are placing increasing pressures on available water resources. There is, in general, no shortage of water on the Earth's land surface, but the areas of surplus water are often located far from major centres of population. Moreover, in many cases these centres prove to be sources of water pollution. Thus, the availability and quality of water are becoming an ever-increasing constraint on human activities, notwithstanding the great technological advances that have been made in the control of surface waters.

STUDY OF THE WATERS CLOSE TO THE LAND SURFACE

Hydrology and its component disciplines

Hydrology deals with that part of the hydrologic cycle from the arrival of water at the land surface as precipitation to its eventual loss from the land either by evaporation or transpiration back to the atmosphere or by surface and subsurface flow to the sea. It is thus primarily concerned with waters close to the land surface. It includes various component disciplines of a more specialized nature. Hydraulics is concerned with the mechanics and dynamics of water in its liquid state. Hydrography is the description and mapping of the bodies of water of the Earth's surface (including the oceans), with a particular concern for navigation charts. Hydrometry involves measurements of surface water, particularly precipitation and streamflow. Hydrometeorology focuses on water in the lower boundary layer of the atmosphere. Groundwater hydrology and hydrogeology have to do with subsurface water in the saturated zone, while soil water physics involves the study of subsurface water in the unsaturated zone. Engineering hydrology is concerned with the design of man-made structures that control the flow and use of water.

Concept of water balance

Underlying all the hydrologic sciences is the concept of water balance, an expression of the hydrologic cycle for an area of the land surface in terms of conservation of mass. In a simple form the water balance may be expressed as

$$S = P - Q - E - G,$$

where S is the change of water storage in the area over a given time period, P is the precipitation input during that time period, Q is the stream discharge from the area, E is the total of evaporation and transpiration to the atmosphere from the area, and G is the subsurface outflow. Most hydrologic studies are concerned with evaluating one or more terms of the water balance equation. Because of the difficulties in quantifying the movement of water across the boundaries of an area under study, the water balance equation is most easily applied to an area draining to a particular measurement point on a stream channel. This area is called a catchment (or sometimes a watershed in the United States). The line separating adjacent catchments is known as a topographical divide, or simply a divide. The following sections describe the study of the different elements of the catchment water balance and the way in which they affect the response of catchments over time under different climatic regimes.

Evaluation of the catchment water balance. *Precipitation.* Precipitation results from the condensation of water from the atmosphere as air is cooled to the dew point, the temperature at which the air becomes saturated with respect to water vapour. The cooling process is usually initiated by uplift of the air, which may result from a number of causes, including convection, orographic effects over mountain ranges, or frontal effects at the boundaries of air masses of different characteristics. Condensation within the atmosphere requires the presence of condensation nuclei to initiate droplet formation. Some of the condensate may be carried considerable distances as cloud before being released as rain or snow, depending on the local temperatures. Some precipitation in the form of dew or fog results from condensation at or near the land surface. In some areas, such as the coastal northwest of the United States, dew and fog drip can contribute significantly to the water balance. The formation of hail requires a sequence of condensation and freezing episodes, resulting from successive periods of uplift. Hailstones usually show a pattern of concentric rings of ice as a result.

Direct measurement of rainfall

Direct measurements of precipitation are made by a variety of gauges, all of which consist of some form of funnel that directs the infalling water to some storage container. Storage gauges simply store the incident precipitation, and the accumulated water is usually measured on a daily, weekly, or monthly basis. Recording gauges allow rates of precipitation to be determined.

Rainfall volumes are usually converted to units of depth—volume per unit area. Measurements obtained from different types of rain gauges are not directly comparable because of varying exposure, wind, and splash effects. The most accurate type of gauge is the ground-level gauge, in which the orifice of the gauge is placed level with the ground surface and surrounded by an antisplash grid. Rain gauge catches decrease as the orifice is raised above the ground, particularly in areas subject to high winds. In areas of significant snowfall, however, it may be necessary to raise the rain gauge so that its orifice is clear of the snow surface. Various shields for the gauge orifice have been tried in an effort to offset wind effects. Wind effects are greater for snow than for rain and for small drops or light rainfall than for large drops.

Indirect measurements of rainfall

An impression of the spatial distribution of precipitation intensity can be achieved through indirect measurements of precipitation, in particular radar scattering. The relationship between rainfall intensity and measured radar signals depends on various factors, including the type of precipitation and the distribution of drop size. Radar measurements are often used in conjunction with rain gauges to allow on-line calibration in converting the radar signal to precipitation amounts. The radar measurements are, however, at a much larger spatial scale. Resolution of five to 10 square kilometres is common for operational systems. Even so, this provides a much better picture of the spatial patterns of precipitation over large catchment areas than has been previously possible. The use of satellite remote sensing to determine rainfall volumes is still in its early stages, but the technique appears likely to prove useful for estimating amounts of precipitation in remote areas.

Measuring snowfall

The measurement of inputs of snow to the catchment water balance is also a difficult problem. The most basic technique involves the snow course, a series of stakes to measure snow depths. Snowfalls can, however, vary greatly in density, depending primarily on the temperature history of snow formation. Accumulated snow changes its density over time prior to melting. Snow density can be measured by weighing a sample of known volume taken in a standard metal cylinder. Other techniques for measuring snowfall include the use of snow pillows, which record the changing weight of snow lying above them, or the use of rain gauges fitted with heating elements, which melt the snow as it falls. These techniques are subject to wind effects, both during a storm event and between events because of redistribution of snow by the wind.

Summary statistics on precipitation are usually produced on the basis of daily, monthly, and annual amounts falling at a given location or over a catchment area. The frequency at which a rainfall of a certain volume occurs within a certain period is also important to hydrologic analysis. The assessment of this frequency, or the recurrence interval of the rainfall from the sample of available data, is a statistical problem generally involving the assumption of a particular probability distribution to represent the characteristics of rainfalls. Such analyses must assume that this distribution is not changing over time, even though it has been shown that in some areas of the world climatic change may cause rainfall statistics to vary. It has long been speculated that rainfalls may exhibit cyclic patterns over long periods of time, and considerable effort has been expended in searching for such cycles. In some areas the annual seasonal cycle is of paramount importance, but demonstrations of longer periodicities have not proved of general applicability.

Patterns of rainfall intensity and duration are of great importance to the hydrologist in predicting catchment discharges and water availability and in dealing with floods, droughts, land drainage, and soil erosion. Rainfalls vary both within and between rainstorms, sometimes dramatically, depending on the type and scale of the storm and its

velocity of movement. Within a storm, the average intensity tends to decrease with an increase in the storm area.

On a larger scale, seasonal variations in rainfall vary with climate. Humid temperate areas tend to have rainfalls that are fairly evenly distributed throughout the year; Mediterranean areas have a winter peak with low summer rainfalls; savanna areas have a double peak in rainfall; and equatorial areas again have a relatively even distribution of rainfall over the course of the year. Average annual rainfalls also vary considerably. The minimum recorded long-term average is 0.76 millimetre at Arica, Chile; the maximum 11,897.36 millimetres at Tutunendo, Colom. The maximum recorded rainfall intensities are 38 millimetres in one minute (Barot, Guadeloupe, 1970); 1,870 millimetres in a single day (Cilaos, Réunion, 1952); and 26,461 millimetres in one year (Cherrapunji, India, 1861).

Interception. When precipitation reaches the surface in vegetated areas, a certain percentage of it is retained on or intercepted by the vegetation. Rainfall that is not intercepted is referred to as throughfall. Water that reaches the ground via the trunks and stems of the vegetation is called stemflow. The interception storage capacities of the vegetation vary with the type and structure of the vegetation and with meteorologic factors. Measurements have shown that up to eight millimetres of rainfall can be intercepted by some vegetation canopies. The intercepted water is evaporated back into the atmosphere at rates determined by the prevailing meteorologic conditions and the nature of the vegetation. In humid temperate areas evaporation of intercepted water can be an important component of the water balance. Forest areas have been shown to have greater interception losses than adjacent grassland areas. This is due to the greater aerodynamic roughness of the forest canopy, resulting in a much more efficient transfer of water vapour away from the surface.

Factors affecting the infiltration rate

Infiltration. When water from a rainstorm or a period of snowmelt reaches the ground, some or all of it will infiltrate the soil. The rate of infiltration depends on the intensity of the input, the initial moisture condition of the surface soil layer, and the hydraulic characteristics of the soil. Small-scale effects such as the presence of a surface seal of low permeability (due to the rearrangement of surface soil particles by rain splash) or the presence of large channels and cracks in the surface soil may be important in controlling infiltration rates. Water in excess of the infiltration capacity of the soil will flow overland as surface runoff once the minor undulations in the surface (the depression storage) have been filled. Such runoff occurs most frequently on bare soils and in areas subject to high rainfall intensities. In many environments rainfall intensities rarely exceed the infiltration capacities of vegetated soil surfaces. The occurrence of surface runoff is then more likely to be generated by rainfall on completely saturated soil.

Evapotranspiration. Rates of evapotranspiration of water back to the atmosphere depend on the nature of the surface, the availability of water, and the "evaporative demand" of the atmosphere (*i.e.*, the rate at which water vapour can be transported away from the surface under the prevailing meteorologic conditions). Estimation of evapotranspiration rates is important in determining expected rates of stream discharge and in controlling irrigation schemes. The concept of potential evapotranspiration—the possible rate of loss without any limits imposed by the supply of water—has been an important one in the development of hydrology. Most direct measurements of rates of potential evapotranspiration are made using standard evapotranspiration pans with an open water surface. Such measurements serve as a useful standard for comparative purposes, but measured rates may be very different from appropriate potential rates for the surrounding surfaces because of the different thermal and roughness characteristics of the vegetation. In fact, the measured pan rate may be affected by the nature of the surrounding surface due to the influence of evapotranspiration on the humidity of the lower atmosphere.

A distinction also must be drawn between potential rates of evapotranspiration and actual rates. Actual rates may be higher than pan rates for a well-watered, rough vegetation canopy. With a limited water supply available from moisture in the soil, actual rates will fall below potential rates, gradually declining as the moisture supply is depleted. Plants can have some effect on rates of evapotranspiration under dry conditions through physiological controls on their stomata—small openings in the leaf surfaces that are the primary point of transfer of water vapour to the atmosphere. The degree of control varies with plant species.

Measuring evapotranspiration

The only reliable way of measuring actual evapotranspiration is to use large containers (sometimes on the order of several metres across) called lysimeters, evaluate the different components of the water balance precisely, and calculate the evapotranspiration by subtraction. A similar technique is often employed at the catchment scale, although the measurement of the other components of the water balance is then necessarily less precise.

Soil moisture. The soil provides a major reservoir for water within a catchment. Soil moisture levels rise when there is sufficient rainfall to exceed losses to evapotranspiration and drainage to streams and groundwater. They are depleted during the summer when evapotranspiration rates are high. Levels of soil moisture are important for plant and crop growth, soil erosion, and slope stability. The moisture status of the soil is expressed in terms of a volumetric moisture content and the capillary potential of the water held in the soil pores. As the soil becomes wet, the water is held in larger pores, and the capillary potential increases.

Methods of measuring soil moisture content

Capillary potential may be measured by using a tensiometer consisting of a water-filled porous cup connected to a manometer or pressure transducer. Soil moisture content is often measured gravimetrically by drying a soil sample under controlled conditions, though there are now available moisture meters based on the scattering of neutrons or absorption of gamma rays from a radioactive source.

The rate at which water flows through soil is dependent on the gradient of hydraulic potential (the sum of capillary potential and elevation) and the physical properties of the soil expressed in terms of a parameter called hydraulic conductivity, which varies with soil moisture in a nonlinear way. Measured sample values of hydraulic conductivity have been shown to vary rapidly in space, making the use of measured point values for predictive purposes at larger scales subject to some uncertainty.

Water also moves in soil because of differences in temperature and chemical concentrations of solutes in soil water. The latter, which can be expressed as an osmotic potential, is particularly important for the movement of water into plant roots due to high solute concentrations within the root water.

Groundwater. Some rocks allow little or no water to flow through; these are known as impermeable rocks, or aquicludes. Others are permeable and allow considerable storage of water and act as major sources of water supply; these are known as aquifers. Aquifers overlain by an impermeable layer are called confined aquifers; aquifers overlain by an unsaturated, or vadose, zone of permeable materials are called unconfined aquifers. The boundary between the saturated and unsaturated zones is known as the water table. In some confined aquifers, hydraulic potentials may exceed those required to bring the water to the surface. These are artesian aquifers. A well drilled into such an aquifer will cause water to gush to the surface, sometimes with considerable force. Continued use of artesian water, however, will cause potentials to decline until eventually the water may have to be pumped to the surface.

Groundwater recharge

The water found in groundwater bodies is replenished by drainage through the soil, which is often a slow process. This drainage is referred to as groundwater recharge. Rates of groundwater recharge are greatest when rainfall inputs to the soil exceed evapotranspiration losses. When the water table is deep underground, the water of the aquifer may be exceedingly old, possibly resulting from a past climatic regime. A good example is the water of the Nubian sandstone aquifer, which extends through several countries in an area that is now the Sahara desert. The water is being used extensively for water supply and irrigation purposes. Radioisotope dating techniques have

shown that this water is many thousands of years old. The use of such water, which is not being recharged under the current climatic regime, is termed groundwater mining.

In many aquifers, groundwater levels have fallen drastically in recent times. Such depletion increases pumping costs, causes wells and rivers to dry up, and, where a coastal aquifer is in hydraulic contact with seawater, can cause the intrusion of saline water. Attempts have been made to augment recharge by the use of waste waters and the ponding of excess river flows. A scheme to pump winter river flows into the Chalk aquifer that underlies London has reversed the downward trend of the water table.

Measuring water-table levels

Water-table levels in an aquifer are measured by using observation wells. Successive measurements of water levels over time may be plotted as a well hydrograph. The hydraulic characteristics of a particular aquifer around a well can be determined by the response of the water table to controlled pumping. Many aquifers exhibit two types of water storage: primary porosity consisting of the smaller pores and secondary porosity or fractures within the rock mass. The latter may make up only a small proportion of the total pore space but may dominate the flow characteristics of the aquifer. They are of particular importance to the movement of pollutants through the groundwater.

Runoff and stream discharge. Runoff is the downward movement of surface water under gravity in channels ranging from small rills to large rivers. Channel flows of this sort can be perennial, flowing all the time, or they can be ephemeral, flowing intermittently after periods of rainfall or snowmelt. Such surface waters provide the majority of the water utilized by humans. Some rivers, such as the Colorado River in the western United States, are used so intensively that often no water reaches the sea. Others flowing through hot, dry areas, as, for example, the Lower Nile, became smaller downstream as they lose water to evaporation and groundwater storage.

Stream discharge is normally expressed in units of volume per unit time (*e.g.*, cubic metres per second), although this is sometimes converted to an equivalent depth over the upstream catchment area. There are a number of techniques for measuring stream discharge. Measurements of velocities using current meters or ultrasonic sounding can be multiplied by the cross-sectional area of flow. Dilution of a tracer can also be used to estimate the total discharge. Weirs of different types are frequently employed at discharge measurement sites. These are constructed so as to give a unique relationship between upstream water level and stream discharge. Water levels can then be measured continuously, usually with a float recorder, to construct a record of discharge over time—namely, a stream hydrograph. Analysis of the hydrographic response to catchment inputs can reveal much about the nature of the catchment and the hydrologic processes within it.

Techniques for measuring stream discharge

Stream discharge data are presented in terms of daily, monthly, and annual flow volumes, though for some purposes (*e.g.*, flood routing) shorter time periods may be appropriate. The frequency characteristics of peak discharges and low flows are also of importance to water resource planning. These are analyzed using some assumed probability distribution in a way similar to rainfalls. A time recording of annual maximum flood is usually used in flood-frequency analysis. For design purposes the hydrologist may be asked to estimate the flood with a recurrence interval of 50 or 100 years or longer. There are few discharge records that are longer than 50 years, so such estimates are almost always based on inadequate data.

Knowledge of the discharge characteristics of catchments is essential to water supply planning and management, flood forecasting and routing, and floodplain regulation. Discharges vary over short lengths of time during storm periods, seasonally with the seasonal changes in evapotranspiration losses, and over longer periods of time as the rainfall regime changes from year to year. Discharge characteristics also vary with climate. In some places discharge represents only a minor component of the catchment water balance, the losses being dominated by evapotranspiration.

Variations in discharge characteristics

The discharge hydrograph that results from a rainstorm represents the integrated effects of the surface and subsurface flow processes in the catchment. Traditionally, hydrologists have considered the bulk of a storm hydrograph to consist of storm rainfall that has reached the stream primarily by surface routes. Recent work using naturally occurring isotope tracers such as deuterium has shown, however, that in many humid temperate areas the bulk of the storm hydrograph consists of pre-event water. This water has been stored within the catchment between storms and displaced by the rainfall during the storm. This suggests that subsurface flow processes may play a more important role in the storm response of catchments than has previously been thought possible.

Modeling catchment hydrology. The availability of high-speed computers has resulted in a widespread use of computer models in the analysis and prediction of hydrologic variables for research as well as for practical design and management purposes. These models vary greatly in type and complexity, from simple computer implementations of methods previously based on manual calculations to attempts to solve the nonlinear partial differential equations describing surface and subsurface flow processes that require much computation. All have their practical limitations.

Use of computer models for analysis and forecasting

The simpler models treat the catchment as a single "lumped" (or undifferentiated) unit. It is clearly not possible to describe hydrologic processes in detail in such a model, and most processes are represented as empirical functional relationships between inputs and outputs. Some "lumped" models do not refer to the internal hydrologic processes of the catchment at all but use systems analysis techniques to relate inputs to outputs. The parameters of such computer models are calibrated by fitting the model to simulate a known discharge record. It is consequently very difficult to interpret parameters derived in this manner in a physically meaningful way or to extend the use of the model to sites where there are no discharge records. Parameter values for ungauged sites can sometimes be estimated from empirical relationships between catchment characteristics and parameter values derived from fitting a model at a number of gauged sites. The uncertainties in such a procedure, however, are high.

The more complex computer models attempt to analyze the internal processes of the hydrologic system in greater detail, taking into account the spatial nature of the catchment, its topography, soils, vegetation, and geology. These are "distributed" models, usually formulated in terms of flow equations for each hydrologic process considered to be important. Some processes such as channel flows and groundwater flows can be described in a reasonably satisfactory way. In the case of other processes, as, for example, flow through the soil and evapotranspiration, hydrologists cannot be so sure of their descriptions. Distributed models tend to have many parameters. In principle, many of these parameters can be measured in the field or can be estimated from the physical characteristics of the catchment. In practice, such models have proved difficult to apply and have not been shown to provide more accurate results than simpler models in spite of their theoretical rigour.

Most models for hydrologic forecasting in practical use today are deterministic; that is to say, given a sequence of inputs to the model, the outputs are uniquely determined. In a probabilistic description of catchment hydrology, the effects of uncertainty in the model inputs, parameters, or descriptive equations must be reflected in a degree of uncertainty in the outputs. Such a model is known as a stochastic model.

Water quality. Natural water quality is a dilute solution of elements dissolved from the Earth's crust or washed from the atmosphere. Its ionic concentration varies from less than 100 milligrams per litre in snow, rain, hail, and some mountain lakes and streams to as high as 400,000 milligrams per litre in the saline lakes of internal drainage systems or old groundwaters associated with marine sediments.

Factors that affect water quality

Water quality is influenced by natural factors and by human activities, both of which are the subject of much hydrologic study. The natural quality of water varies from place to place with climate and geology, with stream discharge, and with the season of the year. After precipitation

reaches the ground, water percolates through organic material such as roots and leaf litter, dissolves minerals from the soil and rock through which it flows, and reacts with living things from microscopic organisms to humans. Water quality also is modified by temperature, soil bacteria, evaporation, and other environmental factors.

Causes of water pollution

Pollution is the degradation of water quality by human activities. Pollution of surface and subsurface waters arises from many causes, but it is having increasingly serious effects on hydrologic systems. In some areas the precipitation inputs to the system are already highly polluted, primarily by acids resulting from the combustion of fossil fuels in power generation and automobiles.

Other serious causes of pollution have been the dumping of industrial wastes and the discharge of untreated sewage into watercourses. Salt spread on roads in winter has resulted in the contamination of subsurface drinking water supplies in certain areas, as, for example, in Long Island, New York. Excess water resulting from deforestation or irrigation return flows that leach salts from soils in semiarid areas are major sources of pollution in the western United States and Western Australia.

STUDY OF LAKES

Limnology as a discipline

Limnology is concerned with both natural and man-made lakes, their physical characteristics, ecology, chemical characteristics, internal energy fluxes, and exchanges with the environment. It often includes the ecology and biogeochemistry of flowing freshwaters. The study of former lakes is known as paleolimnology. It involves inferring the history of a former lake basin on the basis of the evidence contained in the sediments of the lake bed.

Lakes may be formed as a result of tectonic activity, glacial activity, volcanism, and by solution of the underlying rock. Man-made lakes or reservoirs may result from the building of a dam within a natural catchment area or as a complete artificial impoundment. In the former case the reservoir may be filled by natural flow from upstream; in the latter the supply of water must be piped or pumped from a surface or subsurface source. The use of reservoir water for water supply, river regulation, or hydroelectric power generation may cause rapid changes in water levels that would not normally occur in a natural lake. In addition, water is usually drawn from a reservoir at some depth, resulting in a shorter residence time relative to an equivalent natural lake.

The history of lakes. A newly formed lake generally contains few nutrients and can sustain only a small amount of biomass. It is described as oligotrophic. Natural processes will supply nutrients to a lake in solution in river water and rainwater, in the fallout of dust from the atmosphere, and in association with the sediments washed into the lake. The lake will gradually become eutrophic, with relatively poor water quality and high biological production. Infilling by sediments means that the lake will gradually become shallower and eventually disappear. Natural rates of eutrophication are normally relatively slow. Human activities, however, can greatly accelerate the process by the addition of excessive nutrients in wastewater and the residues of agricultural fertilizers. The result may be excessive biomass production, as evidenced by phytoplankton "blooms" and rapid growth of macrophytes such as *Eichhornia*.

The physical characteristics of lakes. The most important physical characteristic of the majority of lakes is their pattern of temperatures, in particular the changes of temperature with depth. The vertical profile of temperature may be measured using arrays of temperature probes deployed either from a boat or from a stationary platform. Remote-sensing techniques are being used increasingly to observe patterns of temperature in space and, in particular, to identify the thermal plumes associated with thermal pollution.

Measuring the vertical profile of lake temperature

In summer the water of many lakes becomes stratified into a warmer upper layer, called the epilimnion, and a cooler lower layer, called the hypolimnion. The stratification plays a major role in the movement of nutrients and dissolved oxygen and has an important control effect on lake ecology. Between the layers there usually exists a zone of very rapid temperature change known as the thermocline. When the lake begins to cool at the end of summer, the cooler surface water tends to sink because it has greater density. Eventually this results in an overturn of the stratification and a mixing of the layers. Temperature change with depth is generally much smaller in winter. Some lakes, called dimictic lakes, can also exhibit a spring overturn following the melting of ice cover, since water has a maximum density at 4° C.

Availability of light with depth

A second important characteristic of lakes is the way that the availability of light changes with depth. Light decreases exponentially (as described by Beer's law) depending on the turbidity of the water. At the compensation depth the light available for photosynthetic production is just matched by the energy lost in respiration. Above this depth is the euphotic zone, but below it in the aphotic zone phytoplankton—the lowest level in the ecological system of a lake—cannot survive unless the organisms are capable of vertical migration.

Patterns of sediment deposition in lakes depend on the rates of supply in inflowing waters and on subsurface currents and topography. Repetitive sounding of the lake bed may be used to investigate patterns of sedimentation. Remote sensing of the turbidity of the surface waters also has been used to infer rates of sedimentation, as in the artificial Lake Nasser in Egypt. In some parts of the world where erosion rates are high, the operational life of reservoirs may be reduced dramatically by infilling with sediment.

Water and energy fluxes in lakes. The water balance of a lake may be evaluated by considering an extended form of the catchment water balance equation outlined above with additional terms for any natural or artificial inflows. An energy balance equation may be defined in a similar way, including terms for the exchange of long-wave and shortwave radiation with the Sun and atmosphere and for the transport of sensible and latent heat associated with convection and evaporation. Heat also is gained and lost with any inflows and discharges from the lake. The energy balance equation controls the thermal regime of the lake and consequently has an important effect on the ecology of the lake.

An important role in controlling the distribution of temperature in a lake is played by currents due either to the action of the wind blowing across the surface of the lake or to the effect of the inflows and outflows, especially where, for example, a lake receives the cooling water from a power-generation plant. In large lakes the effect of the Earth's rotation has an important effect on the flow of water within the lake. The action of the wind can also result in the formation of waves and, when surface water is blown toward a shore, in an accumulation of water that causes a rise in water level called wind setup. In Lake Erie in North America, increases in water level of more than one metre have been observed following severe storms. After a storm the water raised in this way causes a seiche (an oscillatory wave of long period) to travel across the lake and back. Seiches are distinctive features of such long, narrow lakes as Lake Zürich, when the wind blows along the axis of the lake. Internal seiche waves can occur in stratified lakes with layers of different density.

The water quality of lakes. The biological health of a lake is crucially dependent on its chemical characteristics. Limnologists and hydrobiologists are attentive to the dissolved oxygen content of the water because it is a primary indicator of water quality. Well-oxygenated water is considered to be of good quality. Low dissolved oxygen content results in anaerobic fermentation, which releases such gases as toxic hydrogen sulfide into the water, with a drastic effect on biological processes.

Importance of the dissolved oxygen content of lake water

Another major concern of limnologists and hydrobiologists is the cycling of basic nutrients within a lake system, particularly carbon, nitrogen, phosphorus, and sulfate. An excess of the latter in runoff waters entering a lake may result in high concentrations of hydrogen ions in the water. Such acid (low values of pH) waters are harmful to the lake biology. In particular, aluminium compounds are soluble in water at low pH and may cause fish to die because of the response induced in their gills.

STUDY OF THE OCEANS AND SEAS

Oceanography and its component disciplines

Oceanography is concerned with all aspects of the Earth's oceans and seas. Physical oceanography is the study of the properties of seawater, including the formation of sea ice, the movement of seawater (*e.g.*, waves, currents, and tides), and the interactions between the so-called World Ocean and the atmosphere. Chemical oceanography is the study of the composition of seawater and of the physical, biological, and chemical processes that govern changes in composition in time and space. Marine geology deals with the geologic evolution of the ocean basins, while biological oceanography or marine ecology focuses on the plant and animal life of the sea.

The origin of the ocean basins. About 71 percent of the Earth's surface is covered by seawater, with the proportion of sea to land being greater in the Southern Hemisphere (four to one) than in the Northern Hemisphere (1.5 to one). Current theories of plate tectonics explain the development of the present ocean basins in terms of a splitting of a large continental landmass brought about by convective circulation within the Earth's mantle. This circulation causes material to rise from the mantle, resulting in the formation of new lithosphere at the mid-oceanic ridges. Continued ascent of material in these areas has resulted in the movement of older material away from the ridges, a process known as seafloor spreading (see also above). Clear evidence of the broad symmetry of these movements has been produced by studies of the residual magnetism of the rocks of the seafloor, which exhibit successive zones of magnetic reversals parallel to the mid-oceanic ridges. Near the continental masses some of the oceanic material sinks into the mantle in zones of subduction, which are associated with oceanic troughs, deep-focus earthquakes, and volcanic activity.

The physical properties of seawater. The physical properties of seawater depend on the chemical constituents dissolved in it. The spatial variability of seawater composition is only partially known, since many areas of the oceans have not been fully sampled. It has been shown that while the salinity of seawater varies from place to place, the relative proportions of the major constituents remain fairly constant. Chlorine accounts for about 55 percent of dissolved solids, sodium 30.6 percent, sulfate 7.7 percent, magnesium 3.7 percent, and potassium 1.1 percent. The average salinity of seawater is about 35 grams of dissolved salts per kilogram of seawater. Higher values occur in areas where evaporation rates are high, such as the Red Sea (41 grams per kilogram), and in areas where relatively pure water freezes out as sea ice, thereby increasing the salinity of the water below. Variations in salinity may be measured indirectly by measurements of the electrical conductivity of seawater, which also yield an accurate estimate of density. With the electrical conductivity method, it is easy to obtain in situ estimates of density and salinity. Using temperature sensors it is also possible to obtain in situ measurements of seawater temperature, the other very important physical characteristic of seawater. It is primarily variations in temperature and density that drive the circulation of water in the oceans.

Measuring the salinity, density, and temperature of seawater

The density of seawater in high latitudes tends to gradually increase with depth. In tropical areas there is usually a well-mixed layer of uniform density close to the surface above the pycnocline, a layer in which density increases extremely rapidly. Below the pycnocline density continues to increase but much more slowly. The pycnocline is a very stable layer that acts as a barrier to the transfer of water and energy between the surface and subsurface layers.

Seawater has a higher specific heat (about 0.95) than land (0.5 on average), so that changes in the temperature of the oceans are much slower than on land. In fact, the oceans represent a vast store of heat that exercises an important, but not fully understood, control on the variability of climate regimes observed on land. The temperature distribution at the surface of the open seas tends to follow lines of latitude, with warmer waters in tropical regions. Close to the landmasses, the lines of equal temperature (isotherms) become deflected, indicating warm and cold coastal currents. Below the surface there is generally a well-mixed layer of fairly uniform temperature about 50 to 200 metres thick below which lies the thermocline, which may extend to depths of 1,000 metres. Below the thermocline, temperature decreases slowly with depth. A typical temperature profile in equatorial regions would be 20° C down to 200 metres, 8° C at 500 metres, 5° C at 1,000 metres, and 2° C at 4,000 metres.

Plotting the temperature and salinity of a sample of seawater on a graph with linear axes (a T–S diagram) can be a powerful research tool. A mass of fully mixed water having a homogeneous distribution of temperature and salinity would plot as a single point on a T–S diagram. For actual water masses it is common to find that points plotted for samples taken from different depths plot as a curve (sometimes complex) on the diagram. Such curves provide an indication of the mixing between different water masses that is taking place in the profile. T–S curves also are useful for uncovering errors in data.

T–S diagrams

The circulation of the oceans. One major cause of the circulation of waters in the oceans is the difference in the energy budget between the tropics and the poles (the thermohaline circulation). While it is now thought that differences in solar heating have a relatively minor direct effect on ocean circulation, the formation of sea ice and the loss of heat from the oceans at the poles causes a movement of colder, denser water toward the Equator at depth. The major surface currents of the oceans are driven by the surface shear stresses imposed by the wind. These motions are influenced by the topography of the ocean basins and the Coriolis effect due to the Earth's rotation, so that in the Northern Hemisphere the moving water becomes deflected toward the right, while in the Southern Hemisphere toward the left. This results in major clockwise circulations in the North Atlantic (including the Gulf Stream) and the North Pacific, with counterclockwise circulations in the South Atlantic, South Pacific, and Indian oceans. Within the tropics there tends to be a pattern of westward-flowing currents in both the Northern and Southern hemispheres, with an eastward-flowing countercurrent close to the Equator itself. There may also be an eastward-flowing undercurrent at depth. It is certain that there is still much to be learned about the details of ocean circulation, particularly at depth.

The Lagrangian and Eulerian methods of measuring ocean currents

There are two fundamental approaches to measuring ocean currents: the Lagrangian and Eulerian methods. In the Lagrangian method individual parcels of water are tracked using floats or buoys. Satellite-tracked buoys equipped with radio transmitters are now commonly used in the study of surface currents. Currents at depth may be studied with Swallow floats, which are adjusted to be neutrally buoyant at a certain density of seawater. Tracer techniques, such as those involving the use of dyes and discharges of pollutants, may also be employed to track flowing water at least in coastal areas. The greatest number of measurements of surface currents by the Lagrangian method, however, have come from the records of the drift of ships contained in navigation logs.

The Eulerian method consists of measuring the velocity of flow past a fixed point (a moored ship, anchored line, or structure) with a current meter, of which there are a number of different types. Flow velocities may be measured as a function of both depth and time at any site.

Geostrophic method

An indirect method for estimating current velocities is the geostrophic method. It is based on the fact that the movement of water masses away from the sea surface and any solid boundary can be assumed to be frictionless and unaccelerated. Under such conditions the pressure gradient and the effects of gravity and Coriolis forces should balance exactly. The expected rates and directions of flow can then be computed theoretically. It has been shown that the geostrophic currents are good approximations of actual currents.

The hydrodynamics of ocean currents can be described by the dynamic equations of fluid flow. The advent of high-speed digital computers has made it possible to obtain approximate numerical solutions to these equations for many problems of practical interest, including the transient effects of tides. The formation and propagation of waves, together with their refraction in shallow coastal waters, also can be computed numerically.

Biogeochemical cycles in the oceans. The ocean is a great store of chemicals that receives inputs from rivers and the atmosphere and, on average, loses equal amounts to sedimentary deposits on the ocean floor. Biological processes play a large part in processing the chemicals received and in maintaining the remarkable consistency in the composition of seawater. Fortunately this consistency does not extend to all the elements found in seawater. Concentrations of some of the minor, or trace, elements can be used to infer the mixing, biological, and sedimentation processes that occur. Throughout the oceans the major variations in composition are in the upper layers, where the greatest biological activity is found.

Radiometric dating

The use of a number of different radioisotopes in dating sediments and calculating rates of sedimentation and mixing within the oceans have been important in studying the biogeochemical cycles of the oceans. A particularly interesting use of radiometric dating was in investigating the formation of the manganese nodules that occur on certain segments of the seabed and in the underlying sediments. These nodules consist primarily of manganese and iron oxides, even though concentrations of these elements in seawater are very low. Dating techniques have shown that the growth rates of the nodules are on the order of three millimetres per 1,000 years, or 1,000 times less than the accumulation rate of the sediments on which they lie.

Remote sensing of the oceans. One of the fundamental problems faced by oceanographers is the sheer size of the oceans and the consequent need to rely on special surface vessels and submersibles for direct measurements. It can be very costly to operate either type of vessel on long deep-sea expeditions. Moreover, observations from such craft can provide only a partial picture of oceanic phenomena and processes in terms of both space and time. Consequently, there has been considerable interest in taking advantage of remote-sensing techniques in oceanography, particularly those that use satellites. Remote sensing allows measurements to be made of vast areas of ocean repeated at intervals in time.

Satellite observations

The first satellite devoted to oceanographic observations was Seasat, which orbited the Earth for three months in 1978. Its polar orbit made it possible to provide coverage of 95 percent of the major oceans every 36 hours. Seasat carried radiometers for observations at visible, infrared, and microwave wavelengths, along with radar scatterometers, imaging radar, and an altimeter. This array of instruments yielded much data, including an estimation of sea-surface temperatures, net radiation inputs to the sea surface, wave heights, and wind speeds close to the sea surface. In addition, patterns of near-surface sediment movement and other information were derived from an analysis of the satellite images. For further information about remote-sensing techniques used in oceanographic research, see EXPLORATION: *Acoustic and satellite sensing.*

STUDY OF ICE ON THE EARTH'S LAND SURFACE

The scope of glaciology

Glaciology deals with the physical and chemical characteristics of ice on the landmasses; the formation and distribution of glaciers and ice caps; the dynamics of the movement of glacier ice; and interactions of ice accumulation with climate, both in the present and in the past. Glacier ice covers only about 10 percent of the Earth's land surface at the present time, but it was up to three times as extensive during the Pleistocene Ice Age.

The accumulation of ice. Glacier ice forms from the accumulation of snow over long periods of time in areas where the annual snowfall is greater than the rate of melting during summer. This accumulated snow gradually turns into crystalline ice as it becomes buried under further snowfalls. The process can be accelerated by successive melting and freezing cycles. The crystalline ice incorporates some of the air of the original snow as bubbles, which only disappear at depths exceeding about 1,000 metres. Successive annual layers in the ice often can be distinguished by differences in crystalline form, by layers of accumulated dust particles that mark each summer melt season, or by seasonal differences in chemical characteristics such as oxygen isotope ratios. The layers become thinner with depth as the density of the ice increases.

Measurements of oxygen isotope ratios

Oxygen isotope ratios indicate the temperature at which the snow making up the ice was formed. Seasonal variations in isotope ratios not only allow annual layers to be distinguished but also can be used to determine the residence times of melt waters within an ice mass. Long-term variations in isotope ratios can be employed to ascertain temperature variations related to climatic change. An ice core of 1,390 metres taken at Camp Century in Greenland has been used in this way to indicate temperatures during the past 120,000 years, and it shows clearly that the last glacial period extended from 65,000 to about 10,000 years ago. These results have been corroborated by measurements of additional cores from Greenland and Antarctica. In spite of the fact that temperatures may remain below freezing throughout the year, ice accumulation over much of Antarctica is very slow, since precipitation rates are low (they are equivalent to those in many desert areas).

On any glacier there is a long-term equilibrium between accumulation and ablation (losses due to melt runoff and other processes). Continued accumulation eventually causes ice to move downhill, where melt rates are higher. The elevation at which accumulation balances losses changes seasonally as well as over longer periods. In many areas of the world, the annual meltwaters are a crucial part of the water resources utilized by man. In the past it was very difficult to predict amounts of spring melt runoff because of the difficulties in assessing snow accumulation in mountainous terrain. Remote-sensing techniques now allow accumulation over much larger areas to be estimated, and they also offer the possibility of updating those estimates during the melt season.

The movement of glaciers. The mechanisms by which a large mass of ice can move under the effects of gravity have been debated since about 1750. It is now known that some of this movement is due to basal sliding but that the ice itself, a crystalline solid close to its melting point, can flow, behaving like other crystalline solids such as metals. Early measurements of flow velocities were based entirely on surveys of surface stakes, a technique still used today. During the early 19th century the Swiss geologist Louis Agassiz showed that the movement was fastest in the central part of a glacier. Rates of movement are fastest in the temperate glaciers, which have temperatures close to the melting point of ice and include about 1 percent liquid water. (This water constitutes a layer at the bottom of such an ice mass.) Velocities vary through time, quite dramatically at times. Certain glaciers (*e.g.*, the Muldrow and Variagated glaciers in Alaska) are subject to surges of very rapid velocities at irregular periods. The causes of these catastrophic advances are still not well understood.

Modern techniques of studying the movement of glacial ice

Techniques for investigating the movement of ice in the field include studies of the deformation of vertical boreholes and lateral tunnels dug into the ice. The internal structure of glaciers and the Greenland and Antarctic ice caps have also been examined by means of radar sounding. This method works best in cold glaciers where the ice is below its freezing point.

Indirect evidence of the patterns of movement is obtained from the characteristic landforms associated with glaciers, particularly scratched or striated bedrock and moraines composed of rock debris. Such forms also allow the interpretation of former patterns of movement in areas no longer covered by ice.

PRACTICAL APPLICATIONS

Development and management of water resources. Water is essential to many of humankind's most basic activities—agriculture, forestry, industry, power generation, and recreation. As the hydrologic sciences provide much of the knowledge and understanding on which the development and management of available water resources are based, they are of fundamental importance.

In 1965 the United Nations Educational, Scientific and Cultural Organization (UNESCO) initiated the International Hydrological Decade (IHD), a 10-year program that provided an important impetus to international collaboration in hydrology. Considerable progress was made in hydrology during the IHD, but much still remains to be done, both in the basic understanding of hydrologic pro-

cesses and in the development and conservation of available water resources. Many developing countries remain highly susceptible to diseases related to a lack of water supplies of good quality and to the effects of drought. This has been cruelly highlighted in recent times by the severe droughts in the Sahel region of Africa in the periods 1969–74 and 1982–85 (see below).

Misuse of water resources

In the developed countries the ready availability of a supply of good quality water is expected. Yet, even in the most advanced countries, many water sources are not being used wisely. Groundwater levels in certain areas have fallen dramatically since the 1940s, leading to ever higher pumping costs. Other surface and subsurface water sources are becoming increasingly polluted by urban, agricultural, and industrial wastes in spite of increased expenditure on waste-water treatment and legislation of minimum quality standards. Humankind continues to use the oceans as a vast dumping ground for its waste products, even though little is known about the effects of such wastes on marine ecosystems. It is no exaggeration to say that the misuse of water resources will become a major source of conflict between communities, states, and nations in the years to come. Already several disputes over rights to clean water have taken on international significance.

Acidification of surface and subsurface waters

Since the early 1980s the acid rain problem has assumed scientific, economic, and political prominence in North America and Europe. This major environmental problem serves to illustrate the interdependence of the various hydrologic sciences with other scientific disciplines and human activities. As was noted earlier, waste gases (primarily oxides of sulfur and nitrogen) enter the atmosphere from the burning of fossil fuels by automobiles and electric power plants. These gases combine with water vapour in the atmosphere to form sulfuric and nitric acids. When rain or some other form of precipitation falls to Earth, it is highly acidic (often with a pH value of less than 4). The resultant acidification of surface and subsurface waters has been shown to have detrimental effects on the ecology of affected catchments. Areas underlain by slowly weathering bedrock, such as in Scandinavia, the Adirondack Mountains of New York, and the Canadian Shield in Quebec are particularly susceptible. Many lakes in these areas have been shown to be biologically dead. There also is evidence that the growth of trees may be affected, with consequent economic ramifications where forestry is a major activity. The areas most greatly affected may be far downwind of the source of the pollution. A number of countries have claimed that the major sources of acid rain affecting their streams and lakes lie outside their borders.

Research has revealed that in an area susceptible to the effects of acid rain short-lived events can have a particularly damaging effect. These "acid shocks" may be due to inputs of highly acid water from a single storm or to the first snowmelt outflows in which the major part of the pollutant input accumulated over the winter is concentrated. The way in which the chemistry of the input water is modified in its flow through the catchment depends both on the nature of the soils and rocks in the catchment and on the flow paths taken through the system. These interactions are at present poorly understood. It is likely, however, that the attempt to understand the chemical processes within the different flow paths will lead to significant improvements in scientific understanding of catchment hydrology.

Concern over groundwater quantity and quality. Groundwater problems are becoming increasingly serious in many areas of the world. Rapid increases in the rates of pumping of groundwater in many aquifers has caused a steady lowering of water table levels where extraction has exceeded rates of recharge. A notable example is the Ogallala aquifer, a sandy formation some 100 metres thick, which lies beneath the Great Plains from South Dakota to Texas. It has been estimated that as much as 60 percent of the total storage of this huge aquifer has already been extracted primarily for agricultural use. The remaining water, if it continues to be mined in this way, will become more and more expensive to extract. This situation points out the importance of understanding groundwater flow and recharge processes in complex heterogeneous formations so that safe yields of aquifers can be properly predicted.

There are many causes of groundwater pollution; most are the accidental or incidental consequences of human activities (*e.g.*, pollution resulting from the use of artificial fertilizers or saltwater intrusion into coastal aquifers due to excessive pumping). In some cases, however, groundwater may be contaminated because of planned human effort. Subsurface repositories of water, for example, have been considered as possible receptacles for waste products, including radioactive materials. This has resulted in both experimental and model studies of water flows in poorly permeable massive rocks that would be used to store such wastes. The effects of joints and fractures on the very slow transport of contaminants over long periods of time in such rocks is as yet uncertain but must be clarified if this form of storage is to be proved safe.

Studying the causes of droughts and other climatic patterns. Another subject still poorly understood is the occurrence of droughts in areas of highly variable rainfall. In the early 1970s and again in the early 1980s the Sahel region of Africa suffered periods of severe drought, resulting in widespread famine and death. There have been many Sahelian droughts before, but the consequences of the recent droughts have been exacerbated by increased populations of people and grazing animals. The combination of drought and population growth results in desertification. It remains an unanswered scientific question as to whether the deterioration of the Sahel and other marginal lands is part of a long-term natural change or whether it is a result of human activities.

Studies of the effects of El Niño on global climate

Some evidence for long-range interactions in the occurrence of droughts and other climatic regimes comes from studies of the ocean currents. It is known that the oceans are a major controlling influence on climate, but the processes involved remain the subject of active research. Some clues have been revealed by studies of El Niño, a minor branch of the Pacific Equatorial Countercurrent that flows south along the coasts of Colombia and Ecuador where it meets the northward-flowing Peru Current. The cold Peru Current keeps rainfall along the coastal area of Peru very low but maintains a rich marine life, which in turn supports major bird populations and a fishing industry. In certain years El Niño becomes much stronger, forcing the Peru Current to the south. Storms rake the coast, causing flooding and erosion. The sudden change in sea temperatures causes dramatic decreases in plankton production and, consequently, in fish and bird populations. Catastrophic El Niño events occurred in 1925, 1933, 1939, 1944, 1958, and 1983. It is thought that the global changes associated with this last event included severe droughts in Australia and Central America and floods in the southwestern United States and Ecuador. Explanations of the El Niño events have invoked both local and long-range interactions in the circulation of the Pacific winds and currents. The study of such dramatic events, enhanced by remote sensing and computer modeling, is a major stimulus to understanding the general circulation of the Earth's atmosphere and oceans. (K.J.B.)

Atmospheric sciences

Scope of the atmospheric sciences

The atmospheric sciences focus on the structure and dynamics of the Earth's atmosphere. Such mathematical tools as differential equations and vector analysis, together with large computer systems, are used to evaluate the physical and chemical relations that describe the workings of the atmosphere. Planetary science and stellar science are comparable fields of study of the atmospheres of other astronomical bodies.

The atmospheric sciences traditionally have been divided into three topical areas—meteorology, climatology, and aeronomy. In meteorology the focus of study is the day-to-day, hour-to-hour changes in weather within the lower stratosphere and troposphere. Climatology, on the other hand, concentrates on a statistical description of the weather in the same region of the atmosphere but over long periods of time ranging from a month to millions of years. Meteorology is the science from which weather

forecasts are prepared, whereas climatology provides an explanation of why climate differs across the Earth and how it is interrelated with other components of the natural environment. Studies of the atmospheric regions above the lower stratosphere are associated with the field of aeronomy. They deal with such matters as the photochemical processes of the upper atmosphere, ionospheric physics, airglow, magnetospheric storms, and auroral phenomena.

The scope of the atmospheric sciences is indeed broad. Here it is possible only to survey the basic concerns and principal areas of research of the various disciplines involved.

STUDY OF THE EVOLUTION OF THE ATMOSPHERE

The evolution of the Earth's atmosphere remains incompletely understood. Investigators believe that the present atmosphere resulted from a gradual release of gases from the Earth's interior and that it is quite distinct from the primordial atmosphere, which developed by outgassing during the formation of the planet. Current volcanic gaseous emissions include carbon dioxide, sulfur dioxide, chlorine, fluorine, water, and diatomic nitrogen as well as traces of other substances. Approximately 85 percent of the emissions is in the form of water vapour. Carbon dioxide constitutes about 10 percent of the effluent.

Researchers hold that water must have been able to exist in its liquid state during the early evolution of the atmosphere since the oceans appear to have been present for at least 3,000,000,000 years. Because the solar output was about 25 percent less 4,000,000,000 years ago, enhanced levels of carbon dioxide and perhaps ammonia apparently were required to retard long-wave radiative heat loss to space. The initial life forms that evolved in this environment must have been anaerobic (*i.e.*, capable of surviving in the absence of oxygen) and had to have been able to resist the biologically destructive short ultraviolet radiation that was not absorbed by a layer of ozone (0_3) as it is today. Once organisms developed the capability for photosynthesis (in which visible sunlight on plants produces diatomic oxygen [0_2]), oxygen was produced in large quantities, eventually reaching the current levels. This also permitted the ozone layer to develop, as 0_2 was dissociated into monatomic oxygen and recombined with O_2 to form ozone. The capability of primitive plant forms to photosynthesize developed between 2,000,000,000 and 3,000,000,000 years ago. Prior to the emergence of photosynthetic organisms, oxygen was produced in only limited quantities through the decomposition of water vapour into molecular oxygen by ultraviolet radiation from the Sun.

Present composition of the atmosphere

The present composition of the Earth's atmosphere, in terms of total molecules, is diatomic nitrogen (78.08 percent), diatomic oxygen (20.95 percent), argon (0.93 percent), water (from about 0 to 4 percent), and carbon dioxide (0.0325 percent). The inert gases neon, helium, and krypton and other constituents such as nitrogen oxides and sulfur compounds are found in lesser amounts.

STUDY OF SURFACE BUDGETS

Heating by radiation, conduction, and convection. The Earth's atmosphere is bounded at the bottom by water and land. Heating of this surface is accomplished by three physical processes: radiation, conduction, and convection.

Incoming energy

The electromagnetic radiation that influences both the temperature of the atmosphere and that of the surface is commonly divided into two types: insolation from the Sun, which is referred to as shortwave radiation (with predominant wavelengths of 0.39 to 0.76 micrometre); and emittance from the surface and the atmosphere, which is called long-wave radiation (with typical wavelengths of four to 30 micrometres). The wavelength of the emitted electromagnetic radiation depends on the temperature of the radiating body as specified by Planck's law. The Sun, with its surface temperature of around 6,000 K, emits at a much shorter wavelength than the Earth, which has surface and atmospheric temperatures of about 250 to 300 K.

A fraction of shortwave radiation is absorbed by atmospheric gases and warms the air directly. Most of this energy, however, reaches the surface when clouds are not present. Scattering of a fraction of the shortwave radiation, particularly of the shortest wavelengths by air molecules (known as Rayleigh scattering), produces blue skies.

When clouds are present, a large percentage (up to about 80 percent) of the solar insolation is reflected into space (the fraction of back-reflected, shortwave radiation is called the albedo). Of the solar radiation reaching the surface, a fraction is reflected into the atmosphere. Values of the surface albedo range from 0.95 for fresh snow to 0.10 for dark organic soils. On land this reflection occurs entirely at the surface. In water, however, shortwave radiation penetrates to significant depths (as much as several hundred metres) before the insolation is completely attenuated. The heating by solar radiation in water, therefore, is distributed through depth, which results in smaller temperature changes at a given level than would occur with the same insolation over land at the surface.

The magnitude of solar radiation reaching the surface depends on latitude, time of year, time of day, and orientation of the land surface with respect to the Sun. In the Northern Hemisphere north of 23°30′, for example, solar insolation at local noon is less on north-facing slopes than on land oriented toward the south.

Solar radiation consists of two components: direct and diffuse radiation. Direct shortwave radiation is that which reaches a point without being absorbed or scattered from its line of propagation by the intervening atmosphere. The image of the Sun's disk as a sharp, distinct object represents that portion of the solar radiation that reaches the viewer directly. Diffuse radiation, in contrast, reaches the observer only after being scattered from its line of propagation. On an overcast day, for example, the Sun's disk is not visible and all of the shortwave radiation is diffuse.

Long-wave radiation is emitted by the atmosphere and propagates both upward and downward. The magnitude of this radiation reaching the surface depends on the temperature at the height of emission and the amount of absorption between the height of emission and the surface. A larger fraction of the long-wave radiation is absorbed when the intervening atmosphere has large amounts of water vapour and carbon dioxide. Clouds that have a liquid water content on the order of 2.5 grams per cubic metre absorb almost 100 percent of the long-wave radiation within a depth of 12 metres into the cloud. Clouds with less water content require greater depths before complete absorption is attained (*e.g.*, a cloud with a water content of 0.05 grams per cubic metre requires about 600 metres for complete absorption). Clouds that are at least this thick emit long-wave radiation from their base, corresponding to the temperature of the lowest levels of the cloud.

Heat flux by conduction

The magnitude of heat flux by conduction below the surface depends on thermal conductivity and the vertical gradient of temperature in the material beneath the surface. Such soils as dry peat, which has very low thermal conductivity, permit little heat flux, whereas concrete, which has a thermal conductivity almost 100 times as great, allows substantial heat flux. In water, thermal conductivity is relatively unimportant because, in contrast to land surfaces, solar insolation extends to substantial depths into the water, and water can be mixed vertically.

Vertical mixing (convection) occurs in the atmosphere as well as in water. Also referred to as turbulence, this mechanism of heat flux occurs in the atmosphere in two forms. When the surface is warmer than the overlying air, mixing occurs spontaneously to redistribute the heat. This process, termed free convection, occurs when the atmospheric lapse rate of temperature decreases at a rate greater than −0.98° C per 100 metres, the adiabatic lapse rate. In the ocean the temperature increase with depth, which can result in free convection, is dependent on temperature, salinity, and depth. At the surface with a temperature of 20° C and a salinity of 34.85 parts per 1,000, an increase of temperature with depth of more than about 0.19° C per kilometre results in free convection.

Free and forced convection

Mixing also can occur because of the shearing stress of the wind on the surface. As a result of surface friction, the average wind velocities at the surface must be zero unless the surface is moving. Winds above the surface are decelerated when the vertical shear of the wind becomes large enough to cause vertical mixing. This process by which

heat and other atmospheric properties are mixed as a result of wind shear is called forced convection. (Free and forced convection are also referred to as convective turbulence and mechanical turbulence, respectively.) Forced convection occurs either as sensible turbulent heat flux in which heat is directly transported to or from the surface or as latent turbulent heat flux in which heat is used to evaporate water from the surface.

The temperature at the interface of the atmosphere and the surface results from the contributions of heat by radiation, conduction, and convection. The magnitude of these contributions depends on the wind, temperature, and moisture structure in the immediate overlying atmosphere, on the intensity of solar insolation, and on the physical characteristics of the surface.

Other factors affecting atmospheric processes and conditions. The water budget at the air–surface interface is also of crucial importance in influencing atmospheric processes. The surface gains water through precipitation (rain and snow) and by direct condensation and deposition (dew and frost). On land precipitation is often heavy enough for some of it to percolate into the ground or flow as runoff into streams, rivers, lakes, and the oceans. A portion of the precipitation that remains on the surface, such as in puddles or on vegetation, immediately evaporates back into the atmosphere.

Evapotranspiration and evaporation

Liquid water is also converted to water vapour by evapotranspiration as vegetation extracts water from the soil and emits it through stoma on the leaves and by evaporation directly from the surface of the soil when water from below is diffused upward. Evaporation occurs at the surface of water bodies at a rate inversely proportional to the relative humidity just above the surface. Evaporation is rapid in dry air but much slower when the lowest levels of the atmosphere are almost saturated. Evaporation from soil is dependent on the rate at which moisture is supplied by capillary suction within the soil, while evapotranspiration is dependent on the water available to plants within the root zone and whether or not the stoma are open on the leaf surfaces. Water that evaporates and evapotranspires into the atmosphere is often transported long distances over the Earth before it is precipitated.

The input, transport, and removal of water from the atmosphere is part of the hydrologic cycle (see above). At any one time only a very small fraction of the Earth's water is present within the atmosphere. If it were all condensed out, it would only cover the surface of the Earth to an average of about 2.5 centimetres.

Investigators have determined surface budgets for other constituents of the atmosphere as well. The nitrogen budget, for example, involves the chemical transformation of diatomic nitrogen (N_2), which makes up 78 percent of the atmospheric gases, into compounds containing ammonium (NH_4^+), nitrite (NO_2^-), and nitrate (NO_3^-). This conversion, referred to as nitrification, is performed by *Rhizobium* and other nitrifying bacteria that live on the roots of legumes such as peas and clover. Lightning is also a nitrifying agent. The nitrogen compounds are eventually reconverted to N_2 after the plants die or are eaten by denitrifying bacteria. These bacteria, in their consumption of plants and the excreta and corpses of plant-eating animals, perform much of this reconversion to N_2. Some of the compounds, however, are changed back to N_2 by a series of chemical processes associated with ultraviolet light from the Sun. The combustion of petroleum by motor vehicles also produces oxides of nitrogen, which has enhanced the natural concentrations of these compounds. Part of the smog in urban areas is associated with substantially higher levels of these nitrogen compounds.

The sulfur budget is another atmospheric constituent of major importance. Sulfur enters the atmosphere as a result of the weathering of sulfur-containing rocks and by intermittent volcanic emissions. Organic forms of sulfur are incorporated into living organisms and represent an important component in the structure and function of proteins. Sulfur also appears in the atmosphere in the form of the gas sulfur dioxide (SO_2) and as part of particulate matter containing sulfate (SO_4). These forms of sulfur are dry deposited directly or are precipitated onto the Earth's surface. When they are wet, these sulfur compounds transform into caustic sulfuric acid (H_2SO_4).

During the last century significant quantities of sulfur have been released into the atmosphere through the combustion of fossil fuels. In and around regions of urbanization and heavy industrial activity, the enhanced precipitation and deposition of sulfur as sulfuric acid and of nitrogen oxides as nitric acid have been associated with damage to fish populations, forests, and the exteriors of buildings and statues. This is commonly called the acid rain problem. (For details, see above *Development and management of water resources*.)

Carbon budget

The carbon budget in the atmosphere is of critical importance to climate and to life. Carbon appears in the Earth's atmosphere primarily as carbon dioxide (CO_2), which is produced naturally by the respiration of living organisms, during the decay of these organisms, through the weathering of carbon-containing rock strata, and from volcanic emissions. Plants utilize CO_2, water, and solar insolation to convert CO_2 to diatomic oxygen. This process, called photosynthesis, results in about a 3 percent drop in CO_2 concentrations in the Northern Hemisphere during the growing season (spring to fall). CO_2 is also absorbed by the ocean waters with the rate of exchange to the ocean greater for colder waters. Currently CO_2 constitutes about 0.03 percent of the gaseous composition of the atmosphere. In past geologic times CO_2 levels are thought to have been significantly higher than they are today and to have had a significant effect on climate and ecology. During the Carboniferous Period (from about 360,000,000 to 285,000,000 years ago), for example, moderately warm and humid climates and high concentrations of CO_2 were associated with extensive lush vegetation. After these plants died and decomposed, they were converted to sedimentary rocks and became the coal deposits currently used by industry.

The so-called greenhouse effect

In the atmosphere certain wavelengths of long-wave radiation are absorbed and then reemitted by CO_2. Since the lower levels of the atmosphere are warmer than higher layers, the absorption of upward-propagating electromagnetic radiation and the reemission of a portion of it back downward permit the lower atmosphere to remain warmer than it would be otherwise. Erroneously referred to as the greenhouse effect (a greenhouse retains heat primarily because solar radiation enters through the glass, but mixing of air into the greenhouse from above is constrained by the glass), higher concentrations of CO_2 in the air appear to be associated with a warmer lower troposphere.

STUDY OF THE VERTICAL STRUCTURE OF THE ATMOSPHERE

The atmosphere is divided into several distinct layers, which are defined on the basis of whether the temperature increases or decreases with height. The lowest major layer is the troposphere, in which the temperature generally decreases with height. This layer contains most of the Earth's clouds and is the region in which what is known as weather primarily occurs.

The planetary boundary layer. *Characteristics.* The lower levels of the troposphere are usually strongly influenced by the Earth's surface. Known as the planetary boundary layer, they compose the region of the atmosphere in which the surface influences temperature, moisture, and velocity through the turbulent transfer of mass. As a result of surface friction, winds in this layer are usually weaker than they are above that height and blow toward areas of low pressure. The study of the atmospheric structure and dynamics within the layer is referred to as boundary layer meteorology, or micrometeorology.

Micrometeorology

Under clear, sunny skies over land the planetary boundary layer tends to be relatively deep because of the heating of the ground by the Sun and the resultant generation of convective turbulence. During the summer the boundary layer can reach, for example, heights of one to 1.5 kilometres in the eastern United States and up to five kilometres in the southwestern desert region of the country. Under this condition the temperature decreases at the dry adiabatic lapse rate (−9.8° C per kilometre) throughout most of the boundary layer, with a superadiabatic lapse rate of a greater magnitude near the heated surface. In contrast, during clear, calm nights, turbulence tends to cease and

radiational cooling from the surface results in a temperature that increases with height above the surface.

The gradient Richardson number, defined as

$$Ri = \frac{g}{T}\left[\frac{\Delta T}{\Delta z} + 9.8^\circ\ \text{C/km}\right] / \left(\frac{\Delta \vec{V}}{\Delta z}\right)^2,$$

is a commonly used parameter to describe the tendency of the atmosphere to be turbulent. In this expression $\Delta T/\Delta z$ is the temperature lapse rate, $\Delta \vec{V}/\Delta z$ is the velocity shear in the vertical, and g is the gravitation acceleration. The parameter Ri represents the ratio of the generation or suppression of turbulence by buoyant production of energy to the mechanical generation of energy by wind shear.

When a region of the atmosphere has a temperature decrease with height, $\Delta T/\Delta z$, greater in magnitude than the adiabatic lapse rate, turbulence is generated by convective overturning as the warmer, lower level air rises and mixes with the cooler air aloft. Since the environmental lapse rate is greater in magnitude than the adiabatic lapse rate, an ascending parcel of air remains warmer than the surrounding ambient air even though the parcel undergoes expansional cooling. This overturning occurs in the form of bubbles (eddies) of warmer air. The larger bubbles often have sufficient buoyant energy to penetrate the top of the boundary layer and entrain air from aloft into the layer, thereby deepening it. Since, in general, the air aloft has a lapse rate that is less in magnitude than the adiabatic lapse rate, compressional warming of this entrained air results in a heating of the boundary layer. The top of the daytime boundary layer is called the mixed-layer inversion.

The ability of the convective bubbles to penetrate the top of the boundary layer depends on the temperature lapse rate aloft. Since the numerator of Ri is usually positive at those heights, the turbulence of penetrative convective bubbles is rapidly eliminated as the parcel quickly becomes cooler than the ambient environment and negatively buoyant with additional ascent. The height that the boundary layer attains on a sunny day, therefore, is strongly influenced by the intensity of surface heating (which, with strong heating, results in large negative values of Ri near the surface) and the temperature lapse rate just above the boundary layer. The less negative the value of $\Delta T/\Delta z$ above the boundary layer, the greater is the suppression of turbulent bubble penetration.

On clear, calm nights the value of Ri becomes large and positive as radiational cooling results in a temperature increase with height. Turbulence is suppressed by the strong thermal stratification, and nearly laminar flow can result over flat terrain. The depth of the radiationally cooled layer, or nocturnal inversion, depends on factors that include the moisture content of the air, soil and vegetation characteristics, and terrain configuration. In a dry desert, for instance, the nocturnal inversion is higher than in a moister environment. The inversion in a humid environment is lower because more upward-propagating longwave radiation is absorbed by the greater number of water molecules and reemitted downward, thereby preventing the lower levels from cooling as rapidly.

Nocturnal inversion

During windy conditions the mechanical production of turbulence, expressed by the denominator in Ri, becomes important. Turbulence eddies produced by wind shear tend to be smaller in size than the turbulence bubbles produced by buoyancy. Within a few tens of metres from the surface during windy conditions, the wind speed is very accurately represented as a logarithmic function of height. If the winds are sufficiently strong, even with a positive value of Ri, the generation of turbulence by wind shear can dominate the dissipation of turbulence by the stable temperature stratification. Theoretically, the wind shear has to be such that $Ri < 0.25$ for this mechanical turbulence to exist, otherwise laminar flow will result.

Above the boundary layer in the troposphere, Ri tends to be greater than 0.25. The exceptions are near jet streams where large velocity shears exist, in and adjacent to cumuliform clouds where buoyant turbulence is generated as a result of the release of latent heat, and at and just above cloud tops where radiational cooling from the clouds causes a destabilization and generates buoyancy.

Monitoring the planetary boundary layer. Studies of the boundary layer involve both in situ measurements and remote-sensing observations. Meteorologic measurements of the first type include those of temperature, pressure, wind speed, shortwave and long-wave radiative fluxes, and the composition of air. They are conducted with the aid of towers, tethered balloons, and surface data-collection platforms. An assortment of remote-sensing observations are made with active systems, such as Doppler and non-Doppler radars, lidars (light radars), and acoustic sounders. The radar systems measure the back scattering of microwave radiation with wavelengths on the order of three to 10 centimetres. Non-Doppler radar provides estimates only of precipitation intensity, while the Doppler variety can furnish estimates of wind speed and direction as well. Shorter wavelength Doppler radar is often able to measure winds even in clear air. The carbon dioxide infrared lidar—a pulsed laser radar of a wavelength of 10.6 micrometres—can measure wind structure and turbulence within a few tens of kilometres of the instrument. Acoustic sounders enable investigators to monitor the depth and structure of the boundary layer using echo return characteristics. Some remote-sensing observations are made with passive systems, including a pyranometer, which measures direct and diffuse radiation from the Sun, and a pyrheliometer, which samples direct solar radiation only.

Remote-sensing systems

The free atmosphere and the tropopause. *General characteristics and cloud forms.* The region above the boundary layer is commonly referred to as the free atmosphere. Here, winds are not directly retarded by surface friction. Clouds occur most frequently in this portion of the troposphere (the exceptions are fog and clouds that impinge on or develop over elevated terrain).

There are two basic types of clouds: stratiform and cumuliform. Both cloud types develop when clear air ascends, cooling adiabatically as it expands until water begins to condense or deposition occurs. This change in the state of water occurs because cooler air can hold less water than can warmer air.

Classification of clouds

Stratiform clouds form as saturated air is mechanically forced upward, remaining colder than ambient clear air at the same height. In the lower troposphere such clouds are called stratus. Advection fog is a form of stratus cloud whose base lies at the Earth's surface. In the middle troposphere stratiform clouds are called altostratus, while in the upper troposphere the terms cirrostratus and cirrus are applied. The latter refers to thin, often wispy cirrostratus. Precipitating stratiform clouds that extend through a large part of the troposphere are known as nimbostratus.

Cumuliform clouds occur when saturated air is turbulent. Such clouds, with their bubbly, turreted shapes, make it possible to view small-scale, up-and-down motions similar to those that occur, but which are not visually observable, in an unsaturated turbulent planetary boundary layer. Cumulus clouds are often seen with bases near or at the top of the boundary layer as turbulent eddies generated near the Earth's surface reach high enough for condensation to occur.

A cumuliform forms in the free atmosphere if a parcel of air, upon saturation, is warmer than the surrounding ambient atmosphere. Because the parcel is warmer than its surroundings, it accelerates upward, creating the saturated turbulent bubble characteristic of a cumuliform cloud. Cumuliform clouds extending no deeper than the lower troposphere are called cumulus humulis when they are randomly distributed and stratocumulus when they are organized into lines. Cumulus congestus clouds extend into the middle troposphere, while cumulonimbus are the deep precipitating cumuliform clouds that extend throughout the troposphere. Cumulonimbus clouds develop from cumulus humulis and cumulus congestus.

The tropopause, the top of the troposphere, corresponds to the level at which the general decrease in temperature within the troposphere ceases and is replaced by an essentially isothermal layer. In the tropics and subtropics the tropopause is high, often reaching to about 18 kilometres as a result of the vigorous vertical mixing of the atmosphere by thunderstorms. In contrast, in polar regions, where such deep atmospheric turbulence is much less fre-

quent, the tropopause is often as low as eight kilometres. Temperatures at the tropopause height range from −80° C in the tropics to −50° C in the polar regions.

Balloon-borne radiosondes

Meteorologic observations. Radiosondes borne aloft by helium balloons are the primary observation platforms above the boundary layer but within the limits of the troposphere. They measure atmospheric temperature, dew point temperature, and barometric pressure. Since their position is tracked by radar, wind speed and direction as a function of height are also routinely provided. (Radiosondes are sometimes called rawindsondes for this reason.) Meteorologists have been able to produce a long-period data record of the state of the troposphere with radiosonde measurements. The instruments are sent up twice a day simultaneously around the world. Meteorologic observations from radiosondes also are used to initialize the numerical weather prediction models employed for forecasting day-to-day weather conditions.

Another more advanced type of remote-sensing system known as a profiler has been developed to provide almost continuous measurements of wind and, sometimes less accurately, of moisture and temperature throughout the lowest 10 kilometres of the atmosphere. Wind speeds are estimated by upward-directed Doppler radars, while temperature and moisture profiles are evaluated by vertically pointing radiometers that measure electromagnetic emissions of selected wavelengths from various heights in the troposphere. Used in conjunction with satellite-based passive temperature and moisture radiometric soundings and active lidar wind measurements, profilers may eventually render radiosonde soundings obsolete.

Observations from aircraft

Aircraft also provide detailed information about the structure of the atmosphere, particularly during field experiments. Such airplanes as the NOAA P-3 are equipped with a wide array of instruments, including Doppler radar, turbulence sensors, and devices for the in situ measurement of the water and ice content of clouds and their structure. The NOAA P-3 has been used to fly through hurricanes and other deep precipitating cloud systems.

The upper regions of the atmosphere. *Characteristics.* The stratosphere is located above the troposphere and extends up to about 50 kilometres. Above the isothermal layer in the lower stratosphere, temperature increases with height. Temperatures as high as 0° C are observed near the top of the stratosphere. This temperature increase is a result of solar heating as ultraviolet radiation in the wavelength range of 0.200 to 0.242 micrometre dissociates diatomic oxygen. The resultant attachment of single oxygen atoms to 0_2 produces ozone. The observed increase in temperature with height gives rise to strong thermodynamic stability (*i.e.*, large and positive values of *Ri*), with little turbulence and vertical mixing. Because of the warm temperatures and very dry air, the stratosphere is almost cloud free.

The ozone layer

Ozone is produced mainly at tropical and mid-latitudes in the stratosphere; maximum destruction of this form of oxygen occurs in the same locations through catalytic cycles of the nitrogen oxides. Ozone is also transported downward—primarily in the vicinity of the polar front—and poleward, resulting in maximum vertical content in the chemically inactive polar region.

The top of the stratosphere is capped by the stratopause. Above this height, which occurs around levels near 45–50 kilometres and pressures of one millibar, is the mesosphere, where temperatures again decrease with height. Vertical air currents, unlike the stratosphere, are not strongly inhibited in this layer. Ice crystal clouds, known as noctilucent clouds, occasionally form in the upper mesosphere.

Above a height of about 85 to 90 kilometres—the mesopause—temperature again increases with height. The layer above this is the thermosphere, where temperatures range from about 500 K during periods when the Sun is inactive to 2,000 K when it becomes active. The thermopause, defined as the level of transition to a more or less isothermal temperature profile at the top of the thermosphere, occurs at heights of about 250 kilometres during quiet Sun periods to almost 500 kilometres when the Sun is active. Above 500 kilometres, molecular collisions are infrequent enough that temperature is difficult to define.

The part of the thermosphere where charged particles, or ions, are abundant is the ionosphere. The ions result from the removal of electrons from gases by ultraviolet solar radiation. The ionosphere, which extends from about 80 to 300 kilometres in altitude, is an electrically conducting layer from which radio signals can be reflected. Shortwave radio transmissions that can reach around the world take advantage of the ability of the ionospheric layers to reflect certain wavelengths of electromagnetic radiation.

Above about 500 kilometres the motion of ions is strongly constrained by the presence of the Earth's magnetic field. This region of the atmosphere, called the magnetosphere, is compressed by the solar wind on the daylight side of the Earth and stretched outward in a long tail on its night side. The colourful auroral displays often seen in polar latitudes are associated with the generation by solar energy outbursts of high-energy particles in the magnetosphere, which are subsequently injected into the lower ionosphere.

The magnetospheres and auroras

The layer above 500 kilometres is also referred to as the exosphere. In this region at least half of the upward-moving molecules do not collide with one another but rather follow long ballistic trajectories, exciting the atmosphere completely if their escape velocities are high enough. The rate of the molecules lost through the exosphere is critical in determining whether or not the Earth, or other planetary body, retains an atmosphere.

The terrestrial atmosphere is also segmented into a lower layer called the homosphere in which turbulent mixing dominates molecular diffusion of gases. In this region, which occurs below 100 kilometres or so, atmospheric composition tends to be independent of height. Above 100 kilometres, however, in the region designated the heterosphere, the lighter gases are concentrated in the highest layers. Above 1,000 kilometres helium and hydrogen are the dominant species. The relatively heavy gas diatomic nitrogen drops off rapidly with height, and only traces remain at 500 kilometres. This decrease in concentration of heavier gases with height is largest during periods of low solar activity when the temperatures in the heterosphere are relatively low. The transition zone at a height of around 100 kilometres between the homosphere and heterosphere is called the turbopause.

Atmospheric tides

Tides occur in the atmosphere, with the greatest magnitudes in the upper atmosphere, due to direct diurnal heating of the air as the Earth rotates and due to solar and lunar gravitational effects. In contrast to the ocean, the generation of tides by heating is much more important than the gravitational effect.

Observations of the upper atmosphere. Above the usual maximum height of radiosonde measurements (above about 17 kilometres and 100 millibars), rocketsondes, along with rocket-borne grenade and falling-sphere experiments, have been used to monitor thermal structure. Since these measurements are much less frequent than radiosonde observations, however, less is known about the meteorologic phenomena above the tropopause than at lower altitudes. Satellite radiometric soundings also have been used to provide temperature structure down to 60 kilometres or so, though they have less vertical and temporal resolution than in situ measurements. In addition, investigators make use of ground-based radar to measure atmospheric characteristics in the upper atmosphere.

Satellite radiometric soundings

STUDY OF THE HORIZONTAL STRUCTURE OF THE ATMOSPHERE

The motions of the atmosphere and the physical processes involved in air flow are studied by dynamicists. Since the 1960s an increasing number of such investigators in dynamic meteorology have adopted computer models as a basic research tool. Computer models of general global circulation and of various small-scale motion systems (*e.g.*, hurricanes and squall lines) have enabled them to better understand the structure and physics of the atmosphere.

Asymmetrical distribution of solar heating and its effects. The primary driving force on the Earth's atmosphere is the amount and distribution of solar radiation that impinges on the planet. The orbit of the Earth around the Sun is an ellipse with an apogee of 1.47×10^8

kilometres in early January and a perigee of 1.52×10^8 kilometres in early July. The time between the autumnal equinox and the following vernal equinox in the Northern Hemisphere (about September 22 to March 21) is about one week shorter than the rest of the year because of the Earth's elliptical orbit. This results in shorter winters in the Northern Hemisphere than south of the Equator.

The Earth rotates every 24 hours around an axis that is tilted at an angle of 23°30′ with respect to the plane of its orbit. As a result of this tilt, sunshine is more direct on a flat surface at a given latitude during summer than it is during winter in either the Northern or Southern Hemisphere. Poleward of latitude 66°30′, the tilt of the Earth is such that for at least one complete day (at 66°30′) and as long as six months (90°) the Sun is above the horizon during summer and below the horizon during winter.

This asymmetrical distribution of solar heating has the following effect. In winter the high latitudes become very cold in the troposphere as a result of the long nights. In summer the troposphere warms significantly at high latitudes as a result of the long hours of daylight. Yet, because of the oblique angle of the sunlight, the temperatures remain, in general, relatively cool compared to regions in the mid-latitudes during summer. Equatorward of 30° or so, however, substantial and similar radiational heating from the Sun occurs during both winter and summer. The tropical troposphere, therefore, has comparatively little variation in temperature during the entire year.

In the troposphere the demarcation between the cold polar air and the warmer tropical air is usually well defined by the polar front—poleward of the front the air is of polar origin, equatorward it is of tropical origin. The colder polar air is denser than the tropical air, with more than a 30 percent difference in densities at the surface possible for extreme wintertime contrasts. During winter the polar front is generally located at lower latitudes and is stronger than in summer.

The region of greatest solar heating at the surface in the humid tropics results in areas of deep cumulonimbus convection. These cumulonimbus clouds occur because, upon condensation, the clouds are warmer than the surrounding ambient atmosphere. These clouds transport water vapour, sensible heat, and the Earth's rotational momentum to the upper portion of the troposphere.

Atmospheric circulation patterns. Because motion upward into the stratosphere is inhibited by a very stable thermal stratification, the air transported upward by the convection diverges poleward in the upper troposphere. This divergence aloft results in a minimum of pressure at the surface, which is called the equatorial trough. As the air is transported poleward, it is deflected toward the right in the Northern Hemisphere and toward the left in the Southern Hemisphere since it tends to retain the angular momentum of the near-equatorial region. At low latitudes the angular momentum is large because of the Earth's rotation.

Upon reaching about latitude 30° poleward of its region of origin, the air is traveling primarily toward the east. Since all upward motion is constrained by the stratosphere, the air must descend. As the air descends, the resultant compressional warming creates vast regions of strong thermodynamic stability within the troposphere. The sparse precipitation in these regions, a result of stabilization and subsidence, is associated with the great arid regions of the world, such as the Sahara, Atacama, Kalahari, and Sonoran deserts. The accumulation of air due to convergence in the upper troposphere causes deep high-pressure systems called subtropical ridges to occur in these regions.

Upon reaching the lower troposphere, the presence of the Earth's surface requires that the air diverge, with some air moving poleward and the rest equatorward. In either direction the air is deflected to the right in the Northern Hemisphere and to the left in the Southern Hemisphere.

Horizontal deflection of air

The tendency of an air parcel to conserve its momentum causes this horizontal deflection. Such deflection occurs because, according to Newton's first principle, a parcel in motion in a certain direction retains the same motion unless acted on by an exterior force. With respect to the rotating Earth, therefore, a moving parcel that is conserving its momentum (*i.e.*, not acted on by an exterior force) will appear to be deflected with respect to fixed points on the rotating planet. As seen from a fixed point in space, a parcel that is conserving its momentum would be moving in a straight line. This apparent force on air motion is the Coriolis effect. Because of this force, air rotates clockwise around large-scale, low-pressure systems but counterclockwise around large-scale, high-pressure systems in the Northern Hemisphere. The flow direction is reversed in the Southern Hemisphere. In the equatorward-moving flow, this deflection results in northeast winds north of the Equator and southeast winds south of the Equator. These low-level winds are the trade winds. The low-level convergence region of the northeast and southeast trade winds from the two hemispheres is the intertropical convergence zone (ITCZ). The ITCZ corresponds to the equatorial trough and is the mechanism that helps to generate the deep thunderstorms in this pressure trough.

The circulation of ascent in the equatorial trough, poleward movement in the upper troposphere, descent in the subtropical ridges, and equatorward movement in the trade winds is a "direct heat engine" known as the Hadley cell. It is a persistent circulation feature whereby heat from the latitudes of greatest solar insolation is transported to the latitudes of the subtropical ridges. The geographic location of the Hadley circulation moves north and south with the seasons.

Poleward of the subtropical ridges in the lower troposphere, southwesterlies generally occur in the Northern Hemisphere and northwesterlies in the Southern because of the tendency for air motions to conserve absolute angular momentum. Since warm air is being moved poleward at low levels, however, the wind flow is no longer associated with a direct heat engine. The heat that originated in the equatorial trough is consequentially transported further poleward by large, horizontal low-pressure eddies called extratropical cyclones. These extratropical cyclones develop on the polar front when a sufficiently large horizontal gradient of temperature in the lower troposphere develops across the front. The intensity of this temperature gradient is referred to as the baroclinicity of the front.

Developmental stages of extratropical cyclones

Extratropical cyclones are found to have three stages of development: (1) the developing stage in which an undulating wave forms along the front; (2) the mature stage in which sinking cold air sweeps equatorward west of the surface low and ascending warm air moves poleward east of the cyclone; and (3) the occluded stage in which the warm air has become entrained within and moved above the air of polar origin and cut off from the source region of the tropical air. Cyclones that evolve no further than the developing stage are called wave cyclones, while extratropical lows that reach the mature and occluded stages are baroclinically unstable waves. Extratropical storm development is termed cyclogenesis. Surface pressure falls of more than about 24 millibars per day that occasionally occur with rapid extratropical cyclone development are referred to as explosive cyclogenesis and are often associated with major winter storms. Theoretical analysis has shown that the occurrence of baroclinically unstable waves is directly proportional to the magnitude of the temperature gradient, with maximum growth for wavelengths of 3,000 to 5,000 kilometres.

Fronts

Cold fronts occur at the leading edge of polar air moving toward the Equator, while warm fronts are defined at the equatorward surface position of the polar air as it retreats poleward east of the extratropical cyclone. The equatorward-moving air behind the cold front occurs in pools of cold, dense, polar and arctic surface high-pressure systems. Arctic highs are defined to distinguish air of an origin even deeper within the high latitudes than the polar highs. When the polar air is neither retreating nor advancing, the polar front is said to be a stationary front. In the occluded stage, where the cold air west of the surface low-pressure centre advances more rapidly eastward around the cyclonic circulation than the cold air east of the centre moves poleward, the warm, less dense tropical air is forced aloft. The resultant frontal intersection is an occluded front. Fronts of all types always move in the direction toward which the colder air is moving.

Clouds and often precipitation occur poleward of the warm and stationary fronts whenever the poleward-moving, less dense tropical air north of subtropical ridges reaches the latitude of the polar front and is forced upward over the colder air near the surface. Such fronts are defined as active fronts, and rain and snow from them constitute a major part of the precipitation received in middle and high latitudes, particularly in winter.

The polar front slopes toward the colder air with height. This occurs because cold air, being denser, tends to undercut the warmer air of tropical origin. Since the cold air is denser, pressure decreases more rapidly with height poleward of the polar front than on the warmer side. In the middle and upper troposphere, the resultant large horizontal pressure gradient between the polar and tropical air creates strong westerly winds as air circulates around the region of low pressure in the higher latitudes at these heights. The centre of this low-pressure region is the circumpolar vortex. The region of strongest winds, which occurs at the juncture of the tropical and polar air masses, is called the jet stream. Since the temperature contrast between the tropics and the high latitudes is greatest in winter, the jet stream is stronger during that season. In addition, since the mid-latitudes also become colder during winter while tropical temperatures remain relatively unchanged, the westerly jet stream tends to move equatorward during the colder season.

Seasonal variations of the jet stream

The jet stream reaches its greatest velocities at the tropopause. Above that level, lower tropopauses in the polar region than in the tropics result in a reversal of the horizontal temperature gradient in the stratosphere from that found in the troposphere, with warmer temperatures at high latitudes. This causes a weakening of the westerlies with height. At intervals of 20 to 40 months, with a mean of 26 months, a reversal of wind direction occurs at low latitudes in the stratosphere, so that easterly flow develops. This feature is called the quasi-biennial oscillation. A phenomena known as sudden stratospheric warming, apparently a result of strong downward motion, also occurs in late winter and spring at high latitudes and can significantly influence the chemical balance of ozone and other reactive gases in the stratosphere.

Preferred geographic locations exist for the development, movement, and decay of extratropical cyclones and for the presence of centres of the subtropical ridge. During winter in the middle and high latitudes, continents tend to become lower tropospheric high-pressure reservoirs of cold air as heat is radiated out to space during the long nights. In contrast, oceans lose heat less rapidly due to several factors: the large thermal inertia of water; its ability to overturn as the surface cools and become negatively buoyant; and the existence of such ocean currents as the Gulf Stream and the Kuroshio that transport heat from lower latitudes poleward. The lower troposphere over the warmer oceanic areas thus tends to be regions of relative low pressure. As a result of this juxtaposition of cold and warm air, the east sides of continents and the western fringes of oceans in the middle and high latitudes are preferred locations for extratropical storm development. Over the Asian continent, in particular, the cold high-pressure system is sufficiently permanent that a persistent offshore flow called the winter monsoon occurs.

Monsoons and related phenomena

An inverse type of flow develops in summer as the continents heat more than adjacent oceanic areas. Continental areas become regions of relative low pressure, while high pressure in the lower troposphere becomes more prevalent offshore. Persistent lower tropospheric onshore flow that develops over large landmasses as a result of the heating is referred to as the summer monsoon. The leading edge of this monsoon is associated with a trough of low pressure—the monsoon trough. Tropical moisture brought onshore by the monsoon often results in copious rainfall.

The subtropical ridge is segmented into surface high-pressure cells because of the continental effect. In the subtropics large landmasses tend to be relative centres of low pressure as a result of the strong solar heating. Persistent high-pressure cells, therefore, occur over the oceans. The oval shape to these cells causes a different thermal structure in the lower troposphere on their eastern and western sides. On the east, subsidence from the Hadley circulation is enhanced as a result of the tendency for equatorward-moving air to sink in order to preserve its angular momentum on the rotating Earth. On the western sides of the high-pressure cell, poleward-moving air must ascend in order to preserve its momentum. As a result of the enhanced descent in the eastern oceans, landmasses adjacent to these areas are generally deserts such as those in northwestern and southwestern Africa. In spite of being under the descending branch of the Hadley cell, western continental fringes of the subtropical oceans, by contrast, are more likely to have precipitation because the stabilization effect of the subsidence portion of the Hadley cell is minimized by the upward vertical velocity associated with the western side of circular subtropical high-pressure cells.

The aridity found along the west coasts of continents in subtropical latitudes is further enhanced by the influence of the equatorward surface flow around the high-pressure cells on the ocean currents. This flow exerts a shearing stress on the ocean surface, which results in the deflection of the layer of water above the oceanic thermocline to the right in the Northern Hemisphere and to the left in the Southern Hemisphere. This deflection is a result of the tendency for the water to conserve its angular momentum and, therefore, to move westward when displaced toward the Equator. Cold, lower-level water from below the thermocline rises to the surface to replace this offshore ocean flow. These areas of cold, coastal surface waters result in enhanced atmospheric stability in the lower troposphere and an even further reduction in the likelihood for precipitation, though fogs and low stratus clouds are common.

The effects of elevated terrain on climatic conditions

North–south mountain barriers and large massifs (*e.g.*, the Rocky Mountains and the Tibetan Highlands) also influence atmospheric flow. By imposing a barrier to the general westerly flow in mid-latitudes, air tends to be blocked and transported poleward west of the terrain and equatorward east of the obstacle. Air that is forced up the barrier often is sufficiently moist to produce considerable precipitation on windward mountain slopes, while subsidence on the lee slopes produces more arid conditions. The elevated terrain affects the atmosphere as if it were an anticyclone, with the result that warm air is transported further toward the pole west of the terrain. It is also difficult for cold air in the interior to move westward of the terrain; therefore, relatively mild weather exists for the latitude, as, for example, along the west coast of North America. By contrast, east–west mountain barriers (*e.g.*, the Alps) offer little impediment to the general westerly flow, resulting in maritime conditions extending far inland.

A major focus of weather forecasting in the middle and high latitudes is to predict the movement and development of extratropical cyclones, polar and arctic highs, and the location and intensity of subtropical ridges.

STUDY OF CLOUD PROCESSES

Elements of cloud formation. The formation of cloud droplets and cloud ice crystals occurs associated with suspended aerosols of natural and anthropogenic origin, which are ubiquitous in the Earth's atmosphere. In the absence of such aerosols, relative humidities much greater than 100 percent with respect to a flat surface are required for water vapour to condense spontaneously into liquid water or to deposit into ice. The development of clouds without aerosols, which occurs only in a controlled laboratory environment, is referred to as homogeneous nucleation. In the atmosphere, aerosols serve as initiation sites for the condensation or deposition of water vapour. By having a discrete size, they reduce the amount of supersaturation required for water vapour to change its phase. (Air containing water vapour with a relative humidity greater than 100 percent with respect to a flat surface is said to be supersaturated.) Aerosols that are effective as embryonic sites for the conversion of water vapour to liquid water are called cloud condensation nuclei. The larger the aerosol and the greater its solubility, the lower is the supersaturation required for the aerosol to serve as a cloud condensation nuclei. Cloud condensation nuclei in the atmosphere become effective at supersaturations of about 0.1 to 1 percent. The concentration of such nuclei in the

Cloud condensation nuclei and ice nuclei

lower troposphere at a supersaturation of 1 percent range from roughly 100 per cubic centimetre in oceanic air to 500 per cubic centimetre in a continental atmosphere.

Aerosols that are effective for the conversion of water vapour to ice crystals are called ice nuclei. In contrast to cloud condensation nuclei, the most effective ice nuclei are hydrophobic having molecular spacings and a crystallographic structure close to that of ice.

While cloud condensation nuclei are always readily available in the atmosphere, ice nuclei are often deficient. (Examples of condensation nuclei include particles of sodium chloride [salt] and ammonium sulfate, while the clay mineral kaolinite serves as ice nuclei.) Consequently, liquid water that is lifted and cooled below 0° C can often remain liquid at subfreezing temperatures because of the absence of effective ice nuclei. Except for ice crystals that are effective at 0° C, all other ice nuclei become effective only at temperatures lower than freezing. Liquid water at temperatures less than 0° C is referred to as supercooled water. In the absence of any ice nuclei, freezing of supercooled water droplets that measure a few micrometres in radius requires temperatures at or lower than −39° C (a process called homogeneous ice nucleation). When ice nuclei are present, heterogeneous ice nucleation can occur at warmer temperatures.

Ice nuclei are of three types: deposition, contact, and freezing. Deposition nuclei act analogously to condensation nuclei in that water vapour deposits directly as ice crystals on the aerosol. Contact and freezing nuclei, in contrast, are associated with the conversion of supercooled water to ice. Contact nuclei act to convert liquid water to ice by the touching of the contact nuclei aerosol to the supercooled water droplet. Freezing nuclei are absorbed into the liquid water and convert the supercooled water to ice from the inside out.

Precipitation processes in clouds. The evolution of clouds after cloud droplets or ice crystals have formed depends on which phase of water occurs. A cloud in which only liquid water occurs (even at temperatures less than 0° C) is called a warm cloud, and precipitation emanating from such a cloud is said to be the result of warm-cloud processes. In such a cloud, the growth of liquid water from a cloud droplet to a raindrop occurs first as continued condensational growth due to additional water vapour condensing in a supersaturated atmosphere. This process is effective, however, only until the droplet attains a radius of about 10 micrometres. Above this size, further increases in its radius by condensational growth are very slow, since the mass of the droplet increases as the cube of its radius. Subsequent growth thus occurs only when the cloud droplets develop at slightly different rates due to spatial variations in the initial aerosol sizes and solubilities and to magnitudes of supersaturation. Cloud droplets of different sizes fall at different velocities such that cloud droplets of different radii collide. If the collision is strong enough to overcome the surface tension between the two colliding droplets, coalescence occurs with a new, larger single droplet resulting. This process of cloud droplet growth is referred to as collision-coalescence. Warm-cloud rain results when the droplets attain a sufficient size to fall to the ground. Such a raindrop (perhaps about one millimetre in radius) contains on the order of 1,000,000 cloud droplets of 10-micrometre radius. This type of precipitation is common from shallow cumulus clouds over tropical oceans where the concentration of cloud condensation nuclei is small enough that there is only limited competition for the available water vapour.

Warm-cloud processes

A cloud that contains ice crystals is termed a cold cloud, and precipitation resulting from such a cloud is said to be due to cold-cloud processes. In this type of cloud, ice crystals can grow either by deposition directly from water vapour that is supersaturated with respect to ice or as a result of the evaporation of supercooled water and subsequent deposition onto the ice crystal. Because the saturation vapour pressure of liquid water is greater than or equal to the saturation vapour pressure of ice, ice crystals grow at the expense of the liquid water. For example, air that is saturated with respect to liquid water is supersaturated with respect to ice by 10 percent at −10° C and by 21 percent at −20° C. This results in a rapid conversion of liquid water to ice. In a cloud with numerous supercooled cloud droplets, such a substantial and rapid change of phase permits large ice crystals of snowflake size to develop quickly from tiny crystals by depositional growth alone. Clouds that are converted only to ice crystals are known as glaciated clouds. Ice crystals that grow by deposition have much lower densities than solid ice because of the air pockets occurring within the volume of the crystal.

Cold-cloud processes

The specific form of the ice crystals that form depends on the temperature and the degree of supersaturation with respect to ice. At −14° C and a relatively large supersaturation with respect to liquid water, for example, dendritic ice crystals form. This type of ice crystal has growth at the end of radial arms on one or more planes of the crystal. At −40° C and a supersaturation with respect to liquid water of close to zero, hollow ice columns form.

Ice crystals also can grow to precipitation size through aggregation or by riming. Aggregation occurs when the arms of the ice crystals interlock, resulting in a clump. This collection of intermingled ice crystals occasionally can attain sizes of several centimetres in diameter. In riming, supercooled water freezes directly onto ice crystals, causing them to grow; the accumulation of dense ice on the crystals increases their fall velocity. When the riming is substantial, the crystal form of the snowflake is lost and a more or less spherical precipitation-sized particle called graupel results. In cumulonimbus clouds wherein the graupel is repeatedly wetted and then injected back toward high altitudes as a result of strong updrafts, very large graupel, or hail, results.

Aggregation and riming

Frozen precipitation falling to levels much warmer than 0° C reaches the surface as rain. Such cold-cloud rain at the ground is distinguished from warm-cloud rain by its larger size. Melted hailstones, in particular, make a large radius impact when they strike the ground. Cold-cloud rain may refreeze if a layer of subfreezing air exists near the surface. If the freezing occurs in the free atmosphere, sleet or ice pellets is produced. When the freezing occurs only at impact on the ground, freezing rain results.

Procedures of cloud physics research. The study of cloud formation and precipitation processes in clouds is conducted by cloud physicists. The presence of cloud condensation and ice nuclei in air parcels is tested with cloud chambers in which controlled temperatures and relative humidities are specified. In the actual atmosphere, aircraft fly through clouds and collect droplets and ice on collection plates or photograph their presence in the airstream. In the past, identification of the different sizes of droplets and the various types of ice crystals was performed subjectively by researchers, though computer-image assessment procedures now are automating this analysis. At the ground, rainfall impaction molds and snow crystal impressions are made. Hailstones also are collected because an analysis of their structure helps to define the ambient environment in which they formed. Chemical analyses of the cloud droplets, ice crystals, and precipitation are also frequently carried out in order to identify natural and man-made pollutants within the different forms of water.

Cloud chamber studies

STUDY OF CLIMATE AND CLIMATIC CHANGE

As noted earlier, climate is generally conceived of as the expected weather conditions for specific geographic locations. It is defined in terms of averages and as standard deviations around the average.

Local determining factors. Through extensive observations climatologists have found that the primary influences on climate include latitude, degree of continentality, character of the surface, and elevation of a location. Latitude directly influences the intensity of sunlight reaching the ground. In the polar regions, for example, little or no solar radiation reaches the surface in midwinter, while at the Equator the annual variation of solar intensity is small.

The degree of continentality determines the extent to which nearby marine areas moderate temperature variations. Land areas heat and cool relatively rapidly because of the low thermal conductivity of ground surfaces. In contrast, water bodies have a much larger thermal inertia

as a result of the ability of sunlight to penetrate to significant depths and the capability of water to mix vertically. Consequently, diurnal and annual temperature variations over marine areas tend to be much smaller than over continental sites in the same latitude. Observation sites on land but near water bodies tend to have climates that are moderated by the marine influence, particularly when the average wind flow is from the water toward the land. Areas with a large continentality are generally drier than marine areas because such regions are distant from the oceanic source of water vapour to the atmosphere.

The character of the surface also directly influences local climate. A heavily vegetated surface tends to have smaller temperature variations than bare ground. Ground without vegetation converts a relatively large fraction of solar radiation into sensible heating of the air. In contrast, solar radiation on vegetation produces evapotranspiration, which reduces the magnitude of sensible heating. At night bare soil effectively radiates heat into space, thereby producing substantial cooling. Vegetation, on the other hand, helps insulate the ground from this heat loss. Snow-covered ground produces a cooler climate than would otherwise occur because of its greater reflection of incident sunlight. Evapotranspiration from vegetation moistens the atmosphere, making precipitation more likely.

Elevation directly influences climate as temperature normally decreases with height in the troposphere. Elevated areas thus tend to have cooler temperatures than lower sites at the same latitude. Also, solar intensity during the day and long-wave radiative loss at night are larger at higher altitudes because the overlying atmosphere is thinner. This often results in larger diurnal variations in temperature at higher elevations than occur closer to sea level.

The relation of precipitation patterns to general circulation features

The climatic distribution of precipitation can be related to the major general circulation features of the Earth. Air ascends on the average in the intertropical convergence zone and along the polar front. The intertropical convergence zone, which separates air of northern and southern hemispheric origin, is associated with deep thunderstorms, while migratory extratropical cyclones propagate along the polar front, producing large-scale organized areas of precipitation. Locations close to these major weather features throughout the year tend to have substantial precipitation evenly distributed over the seasons.

Descending motion (subsidence) is associated with the subtropical ridge and the circumpolar arctic high-pressure region. Little precipitation occurs in those areas that are dominated by these weather features. Arid climatic regions such as the Sahara, Kalahari, and Sonoran deserts result directly from the persistence of subtropical ridges over these areas throughout the year. Regions that are influenced by the subtropical ridge only during the summer (*e.g.*, southern California, southwestern Australia, and the Mediterranean area) but are often in the vicinity of the polar front during winter have a dry summer/wet winter climate pattern. The Antarctic continent is very dry because of its location relative to the subsidence of the circumpolar Antarctic high-pressure region.

Climatic change and its causes. Humans have adjusted agricultural and other activities to the current climatic configuration of the Earth. Climatic conditions, however, change with time, as, for example, from the apparent warm, humid global conditions of the Carboniferous Period to the widespread continental glaciation of the Pleistocene Epoch. Using fossils and other geologic evidence (*e.g.*, erosional landforms, shoreline features, and glacial deposits), paleoclimatologists have demonstrated that the periodic occurrence of extensive glaciation separated by long periods of a warm global climate is a recurrent characteristic of the Earth. The causes of these climatic changes have been attributed to a variety of mechanisms, including increased volcanic emissions that have been associated with the blocking of sunlight and the resultant cooling at the surface. Periodic reductions in solar output also have been suggested as the cause of global cooling.

Findings of paleoclimatological research

The movement of the continents over the Earth's surface over long time periods is thought to have caused different global climatic patterns. This migration of the landmasses, known as continental drift, has been invoked to explain geologic evidence of tropical fauna in Antarctica and of glaciers at low altitudes in Africa.

Variations over time of the obliquity of the Earth's axis with respect to its orbital plane, the eccentricity of the orbit, and the precession of the axis directly influence the distribution of solar radiation over the planet and therefore the climate. The obliquity of the Earth varies between 24°36′ and 21°39′ from its current value of 23°30′ over a period of approximately 40,000 years. The eccentricity ranges between about 0 to 0.05 from its current value of 0.016 over a time period of about 92,000 years, while the precession of the axis requires from 16,000 to 26,000 years to make a complete circle. The most pronounced difference between winter and summer seasons occurs with a large obliquity and a large eccentricity such that winter occurs when the Earth is farthest from the Sun.

Effects of human activities on climate

Over the last few hundred years, humankind has been directly influencing global and local climate. The development of urban areas has created different ground characteristics that have resulted in urban heat islands in which cities are warmer, particularly at night, than the surrounding countryside. The input of carbon dioxide (CO_2) into the atmosphere through industrial activities has been suggested to be associated with warming near the surface as additional long-wave radiation emitted at the surface is absorbed by the CO_2 and radiated back toward the surface. In the period 1958–75, for example, the average CO_2 level of the atmosphere increased at a rate of about 1.7 parts per million per year. There is concern that by the year 2100 the enhanced CO_2 level resulting from industrial activity will increase the average global temperatures by as much as 5° C, with the greatest impact at high altitudes.

Aerosols are also released into the atmosphere by industrial and other human activities. Climatologists have suggested that anthropogenic-generated aerosols could alter the Earth's radiation budget, perhaps even counteracting the warming effect of CO_2. The ability of additional aerosols to heat or to cool the Earth's atmosphere depends on their vertical and horizontal distribution, and their concentration, size, and chemistry.

The addition to the atmosphere of anthropogenic aerosols, which serve as additional cloud condensation and ice nuclei, also could alter the percentage of the Earth covered by clouds. Increased concentrations of cloud condensation nuclei, for instance, would reduce the average droplet size within a cloud, making the droplets more colloidally stable and thus less likely to precipitate. Such clouds are likely to persist longer, resulting in enhanced reflection of sunlight during the day (*i.e.*, a cooling effect) but a reduction of long-wave radiational cooling at night if the clouds are in the low to middle troposphere. The net effect on global climate remains unclear.

PRACTICAL APPLICATIONS

Weather forecasting. Among the various applications of the atmospheric sciences, weather forecasting is of considerable immediate importance. A necessary condition to making accurate predictions of future weather conditions is an adequate characterization of the pattern of winds, temperatures, moisture, and pressure that currently prevail in the troposphere across the globe. Data for such a meteorologic analysis is obtained by the aforementioned balloon-borne radiosondes that are released twice daily (at 0000 and 1200 Greenwich Mean Time) around the world. Global analyses of temperature, moisture, and winds are routinely prepared for the surface as well as for the standard pressure levels of 850, 700, 500, 300, and 200 millibars. Weather information is shared worldwide via the Global Telecommunications System (GTS).

Numerical weather prediction models

The principal tools used in weather forecasting include numerical weather prediction models. Employing mathematical representations of the physical conservation laws of motion, heat, mass, and moisture in the form of nonlinear, partial differential equations, synoptic meteorologists are able to approximate relations for solution on a three-dimensional grid mesh and to integrate them forward in time. The grid mesh corresponds to the domain of interest, which can represent the entire Earth (a global model) or a local region such as North America (a limited

area model). Exact solutions of the nonlinear equations are, in general, not possible, necessitating their evaluation on a grid. Large, high-speed supercomputers (*e.g.*, the CYBER 205 systems of the United States National Meteorological Center and of the British Meteorological Office, and the CRAY systems of the U.S. National Center for Atmospheric Research and of the European Centre for Medium Range Forecasting) are required to perform the vast number of calculations associated with the integration of atmospheric models forward in time. The use of such supercomputer-integrated models appears to have made it possible to accurately predict pressure fields and temperature anomalies and, to a lesser extent, precipitation at least five to seven days in advance. Public forecasts of weather beyond 12 hours are almost exclusively based on the predictions and statistically derived products of these complex models.

Reliance on weather satellite, radar, and surface observations

For time periods of less than 12 hours, radar, satellite, and surface observations are used extensively to characterize details of local weather for its short-term extrapolation into the future. In a form of prediction known as nowcasting, these sources of information are also used to fill in spatial variations in weather that are both unobservable and incapable of being predicted in large-scale weather forecasting models with horizontal grid-mesh distances of 80 kilometres or more. Tracking a hurricane and following the evolution of a squall line are examples in which high-resolution observation platforms are used to monitor weather systems. Numerical prediction models with smaller grid meshes (on the order of one to 20 kilometres) have been applied over several-hundred-kilometre by several-hundred-kilometre areas to predict weather 12 to 18 hours ahead. This scale of atmospheric motion is defined as the mesoscale.

Weather modification. In addition to predicting weather, man is seeking to deliberately alter atmospheric conditions. Most past and present efforts to modify the weather involve attempts to augment precipitation, suppress hail and fog, and weaken hurricanes.

Cloud seeding

Precipitation increases have been sought by both static and dynamic cloud seeding. One technique of static cloud modification involves introducing modest amounts of silver iodide or solid carbon dioxide (Dry Ice), from aircraft or ground-based rockets, into subfreezing levels of a liquid water cloud in which natural ice nuclei are deficient. Silver iodide, which has a crystal lattice structure similar to that of ice, provides artificial ice nuclei, while Dry Ice directly freezes the liquid water. Because snow crystals grow rapidly in a subfreezing liquid water environment, precipitation results. This mechanism of cloud seeding is used in stratiform clouds upwind of mountainous areas to increase snowpack. It also is used to dissipate subfreezing fog at airports through the conversion of the fog droplets to snow crystals, which precipitate to the ground.

Dynamic cloud seeding involves the massive injection of silver iodide into a subfreezing layer of a growing cumulus cloud composed of water droplets. The rapid conversion of the supercooled water to ice—and associated release of the latent heat of fusion—causes enhanced buoyancy and growth of the cumulus cloud into a larger system than it otherwise would be. Greater precipitation is associated with deeper cumulus clouds. Also, by judiciously seeding adjacent cumulus clouds, it may be possible to promote their merger into large cumulonimbus systems.

The injection of large quantities of silver iodide into potential hailstorms also has been pursued. The hypothesis is that a larger number of ice crystals from which hailstones develop will result in smaller, more numerous hailstones as the competition for the water available among ice particles is greater. Since the hail is smaller it is more likely to melt before reaching the surface and doing damage to crops.

Besides such deliberate attempts at weather modification, humans are inadvertantly altering weather and climate as well. Changes in ground surface characteristics by urbanization, agriculture, and other activities have altered the heat and moisture budget at the surface. The clearing of forests in the Amazon Basin, for example, is believed to be increasing the carbon dioxide content of the atmosphere due to the loss of photosynthetic biomass. The burning of fossil fuels also releases carbon dioxide and is thought to be contributing to the overall increase. Carbon dioxide is an effective absorber and remitter of long-wave radiation released from the Earth, so that higher levels of CO_2 are suspected to cause global warming, possibly to the extent of melting substantial portions of the Greenland and Antarctic ice caps. At the same time, the burning of fossil fuels, along with other industrial activities, releases vast quantities of airborne particulates. Because of the continuous emission of these air pollutants into the tropospheric wind circulation and cumulus cloud venting into the mid- and upper troposphere, more solar radiation may be reflected back into space than would otherwise occur, resulting in a tendency for global cooling. This would certainly be the case if the particulate matter reaches the upper troposphere and stratosphere where its residence time would be of long duration.

Problems associated with the buildup of CO_2 and particulate matter in the atmosphere

Cooling associated with enhanced turbidity from industrial particulates in the atmosphere could balance the warming that is suggested to result from increased CO_2 concentrations. Unfortunately both effects are expected to become much larger during the next century as developing countries industrialize. Should either effect become dominant over the other, a rapid deterioration of the climate could result. (R.A.Pi.)

JAESCHKE, *Chemistry of the Unpolluted and Polluted Troposphere* (1982). (*Air pollution meteorology*): An excellent though now somewhat dated work is JOHN H. SEINFELD, *Air Pollution: Physical and Chemical Fundamentals* (1975). Other useful texts include ARTHUR C. STERN (ed.), *Air Pollution*, vol. 1, *Air Pollutants, Their Transformation and Transport*, 3rd ed. (1976), and vol. 4, *Engineering Control of Air Pollution*, 3rd ed. (1977); and F.T.M. NIEUWSTADT and H. VAN DOP (eds.), *Atmospheric Turbulence and Air Pollution Modelling* (1982, reprinted 1984). (*Synoptic meteorology*): SVERRE PETTERSSEN, *Weather Analysis and Forecasting*, 2nd ed., 2 vol. (1956), is excellent, but much of the material is dated. The best sources are publications of public and military weather services, including RALPH K. ANDERSON *et al.*, *Application of Meteorological Satellite Data in Analysis and Forecasting* (1969, reprinted 1974); UNITED STATES. DEPARTMENT OF THE AIR FORCE. AIR WEATHER SERVICE, *The Use of the Skew T, Log P Diagrams in Analyzing and Forecasting* (1969); and ROBERT C. MILLER, *Notes on Analysis and Severe-Storm Forecasting Procedures of the Air Force Global Weather Central*, rev. ed. (1972). A new forecasting concept is discussed in K.A. BROWNING (ed.), *Nowcasting* (1982). Mesoscale atmospheric systems are discussed in B.W. ATKINSON, *Meso-Scale Atmospheric Circulations* (1981). A summary of current work in applied areas of meteorology, including weather forecasting, is DAVID D. HOUGHTON (ed.), *Handbook of Applied Meteorology* (1985). (*Atmospheric modeling*): The use of computer models to simulate atmospheric features is treated in GEORGE J. HALTINER and ROGER TERRY WILLIAMS, *Numerical Prediction and Dynamic Meteorology*, 2nd ed. (1980); and ROGER A. PIELKE, *Mesoscale Meteorological Modeling* (1984). (*Remote sensing*): RICHARD J. DOVIAK and DUŠAN S. ZRNIC, *Doppler Radar and Weather Observations* (1984); E.C. BARRETT and L.F. CURTIS, *Introduction to Environmental Remote Sensing*, 2nd ed. (1982); E.E. GOSSARD and R.G. STRAUCH, *Radar Observation of Clear Air and Clouds* (1983); and T.D. ALLAN (ed.), *Satellite Microwave Remote Sensing* (1983). (*Weather modification*): Useful summaries are available in W.N. HESS, *Weather and Climate Modification* (1974); and ARNETT S. DENNIS, *Weather Modification by Cloud Seeding* (1980).

(R.A.Pi.)

Earthquakes

An earthquake is a sudden disturbance within the Earth manifested at the surface by a shaking of the ground. This shaking, which accounts for the destructiveness of an earthquake, is caused by the passage of elastic waves through the Earth's rocks. These seismic waves are produced when some form of stored energy, such as elastic strain, chemical energy, or gravitational energy, is released suddenly.

Few natural phenomena can wreak as much havoc as earthquakes. Over the centuries they have been responsible for millions of deaths and an incalculable amount of damage to property. While earthquakes have inspired dread and superstitious awe since ancient times, little was understood about them until the emergence of seismology at the beginning of the 20th century. Seismology, which involves the scientific study of all aspects of earthquakes, has yielded answers to such long-standing questions as why and how earthquakes occur. These matters are discussed in this article, as are the distribution, size, and effects of earthquakes.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 212, 213, and 231, and the *Index*.

The article is divided into the following sections:

GENERAL CONSIDERATIONS

Principal types of seismic waves. Seismic waves generated by an earthquake source are commonly classified into three main types. The first two, the *P* and *S* waves, are propagated within the Earth, while the third, consisting of Love and Rayleigh waves, is propagated along its surface (Figure 1). The existence of these types of seismic waves was predicted during the 19th century, and modern investigators have found that there is a close correspondence between such theoretical calculations and seismographic measurements of the waves.

P and *S* waves

The *P* (or primary) waves travel through the body of the Earth at the highest speeds. They are longitudinal waves that can be transmitted by both solid and liquid materials in the Earth's interior. With *P* waves, the particles of the medium vibrate in a manner similar to sound waves, and the transmitting rocks are alternately compressed and expanded. The other type of body wave, the *S* (or secondary) wave, travels only through solid material within the Earth. With *S* waves, the particle motion is transverse to the direction of travel and involves the shearing of the transmitting rock.

Because of their greater speed, the *P* waves are the first to reach any point on the Earth's surface. The first *P*-wave onset starts from the spot where an earthquake originates. This point, usually at some depth within the Earth, is called the focus, or hypocentre. The point immediately above the focus at the surface is known as the epicentre.

Love and Rayleigh waves

Love and Rayleigh waves are guided by the free surface of the Earth. They follow along after the *P* and *S* waves have passed through the body of the planet. Both Love and Rayleigh waves involve horizontal particle motion, but only the latter type has vertical ground displacements. As Love and Rayleigh waves travel, they disperse into long wave trains, and at substantial distances from the source they cause much of the shaking felt during earthquakes.

Properties of seismic waves. At all distances from the focus, the mechanical properties of the rocks, such as incompressibility, rigidity, and density, play a role in the speed with which the waves travel and the shape and duration of the wave trains. The layering of the rocks and the physical properties of surface soil also affect these characteristics of the waves. In most cases, elastic behaviour occurs in earthquakes, but the shaking of surface soils from the incident seismic waves sometimes results in nonelastic behaviour, including slumping (*i.e.*, the downward and outward movement of unconsolidated material) and the liquefaction of sandy soil.

When a seismic wave encounters an interface or boundary that separates rocks of different elastic properties, it undergoes reflection and refraction. There is a special complication if a conversion between the wave types occurs at such a boundary: either an incident *P* or *S* wave can yield in general reflected *P* and *S* waves and refracted *P* and *S* waves. Boundaries between structural layers also give rise to diffracted and scattered waves. These additional waves are in part responsible for the complications observed in ground motion during earthquakes. Modern research is concerned with computing, from the theory of waves in complex structures, synthetic records of ground motion that are realistic in comparison with observed ground shaking.

The frequency range of seismic waves is large. Seismic waves may have frequencies from as high as the audible range (greater than 20 hertz [Hz]) to as low as the free oscillations of the whole Earth, with gravest period being 54 minutes (*i.e.*, the Earth vibrates in various modes, and the mode with the lowest pitch takes 54 minutes to complete a single vibration; see below *Long-period oscillations of the globe*). Attenuation of the waves in rock imposes high-frequency limits, and in small to moderate earthquakes measured surface waves have frequencies extending from about one to 0.005 Hz.

The amplitude range of seismic waves is also great in most earthquakes. The displacements of the ground extend from 10^{-10} to 10^{-1} metres. In the greatest earthquakes, the ground amplitude of the predominant *P* waves may be several centimetres at periods of two to five seconds. Very close to the seismic sources of great earthquakes, investigators have measured large wave amplitudes with

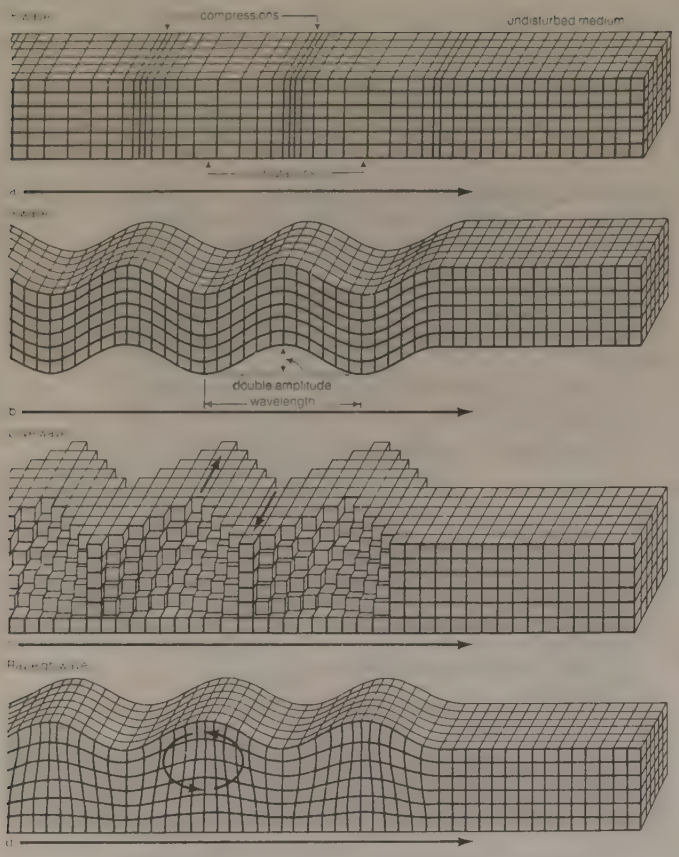

Figure 1: Ground motions in four main types of earthquake waves.

accelerations to the ground exceeding that of gravity at high frequencies and ground displacements of one metre at low frequencies.

Seismic instruments and systems. Ground motion in earthquakes and microseisms (small, often long-continuing oscillations of the ground that do not originate in earthquakes) are both recorded by seismographs. Most of these instruments are of the pendulum type. Still in use today are mechanical seismographs that have a pendulum of large mass (up to several tons) and that produce seismograms by scratching a line on smoked paper on a rotating drum. In more advanced instruments, seismograms are recorded by means of a ray of light from the mirror of a galvanometer through which passes an electric current generated by electromagnetic induction when the pendulum of the seismograph moves. Technological developments, notably in electronics, have given rise to high-precision pendulum seismometers and sensors of ground motion. In these instruments, the electric voltages produced by motions of the pendulum or the equivalent are passed through electronic circuitry to amplify the ground motion for more exact readings.

Major types of seismographs

Generally speaking, seismographs are divided into three types: short period; long (or intermediate) period; and ultra-long period, or broad-band, instruments. Short-period instruments are used to record *P*- and *S*-body waves with high magnification of the ground motion. For this purpose, the seismograph response is shaped to peak at a period of about one second or less. The long- or intermediate-period instruments of the type used by the World-Wide Standard Seismographic Network (WWSSN; see below) have a response maximum at about 20 seconds. Again, in order to provide as much flexibility as possible for research work, the trend has been toward the operation of very-broad-band seismographs, often with digital representation of the signals. This is usually accomplished with very-long-period pendulums and electronic amplifiers that pass signals in the 0.005 to 50 Hz band.

When seismic waves close to their source are to be recorded, special design criteria are needed. Instrument sensitivity must ensure that the largest ground movements remain on scale. For most seismological and engineering purposes the wave frequency is high, and so the pendulum or its equivalent can be small. For comparison, displacement meters need a long free period and pendulum with consequent instability. Accelerometers that measure the rate at which the ground velocity is changing have an advantage for strong-motion recording, because they allow integration to be carried out to estimate ground velocity and displacement. The ground accelerations to be registered range up to twice gravity ($2g$). Recording such accelerations can be easily accomplished with short torsion suspensions or force-balance mass-spring systems.

Because many strong-motion instruments need to be placed at unattended sites in ordinary buildings for periods of months or years before a strong earthquake occurs, they usually record only when a trigger mechanism is actuated with the onset of motion. Solid-state memories are now used, particularly with digital recording instruments, making it possible to preserve the first few seconds before the trigger starts the permanent recording. In the past, recordings were usually made on film strips for up to a few minutes' duration. In present-day equipment, digitized signals are stored directly on magnetic cassette tape or on a memory chip. In most cases absolute timing has not been provided on strong-motion records but only accurate relative time marks; the present trend, however, is to provide Universal Time (the local mean time of the prime meridian) by means of special radio receivers or small crystal clocks.

The prediction of strong ground motion and response of engineered structures in earthquakes depends critically on measurements of the spatial variability of earthquake intensities near the seismic wave source. In an effort to secure such measurements, special arrays of strong-motion seismographs are being installed in areas of high seismicity around the world. Large-aperture seismic arrays (linear dimension on the order of one to 10 kilometres) of strong-motion accelerometers can now be used to improve estimations of speed, direction of propagation, and type of seismic wave components. Like an array of radio telescopes, a seismic array allows wave correlations for consecutive time and frequency intervals so that variations in shaking over small-to-moderate distances can be measured.

Seismic arrays

Finally, because 70 percent of the Earth's surface is covered by water, there is a need for ocean-bottom seismometers to augment the global land-based system of recording stations. Research is under way to determine the feasibility of extensive long-term recording by instruments on the seafloor. Japan already has a semipermanent seismograph system of this type. The system was placed on the seafloor off the Pacific coast of central Honshu in 1978 by means of a cable.

Because of the mechanical difficulties of maintaining permanent ocean-bottom instrumentation, different systems have been considered. These include instruments that are placed in an ocean-bottom package; signals from the instruments are either transmitted to the ocean surface for retransmission by auxiliary apparatus or transmitted via cable to a shore-based station. Another system is designed to release automatically its recording component, allowing it to float to the surface for later recovery.

The use of ocean-bottom seismographs should yield much improved global coverage of seismic waves and provide important information on the seismicity of oceanic regions. Ocean-bottom seismographs will enable investigators to determine the details of the crustal structure of the seafloor and, because of the relative thinness of the oceanic crust, should make it possible for them to collect clear seismic information about the upper mantle. Such systems are also expected to provide new data on focal mechanism, on the origin and propagation of microseisms, and on the nature of ocean-continent margins.

EFFECTS OF EARTHQUAKES

Primary effects. Earthquakes have varied effects, including changes in geologic features, damage to man-made structures, and impact on human and animal life.

Geomorphological changes caused by earthquakes

Geomorphological changes are often caused by an earthquake: *e.g.*, movements—either vertical or horizontal—along geological fault traces; the raising, lowering, and tilting of the ground surface with related effects on the flow of groundwater; liquefaction of sandy ground; landslides; and mudflows. The investigation of topographical changes is aided by geodetic measurements, which are made systematically in a number of countries seriously affected by earthquakes.

Earthquakes can do significant damage to buildings, bridges, pipelines, railways, embankments, and other man-made structures. The type and extent of damage inflicted are related to the strength of the ground motions and to the behaviour of the foundation soils.

In the most intensely damaged region, called the meizoseismal area, the effects of a severe earthquake are usually complicated and depend on the topography and the nature of the surface materials; they are often severer on soft alluvium and unconsolidated sediments than on hard rock. At distances of more than 100 kilometres (62 miles) from the source, the main damage is caused by surface waves. In mines there is frequently little damage below depths of a few hundred metres even though the surface immediately above is considerably affected.

Further effects of interest are the occurrence of earthquake sounds and lights. The sounds are generally low-pitched and have been likened to the noise of an underground train passing through a station. The occurrence of such sounds implies the existence of significant short periods in the *P* waves in the ground (a wave period is the length of time between the arrival of successive crests in a wave train). Occasionally luminous flashes, streamers, and balls are seen in the night sky during earthquakes. These lights have been attributed to electric induction in the air along the earthquake source.

Intensity scales. The level of violence of seismic shaking varies considerably over the affected area. This intensity is not capable of simple quantitative definition and, particularly before seismographs capable of accurate measurement of ground motion were developed, the shaking was estimated by reference to intensity scales that describe the effects in qualitative terms. Subsequently, the divisions in these scales have been associated with accelerations of the local ground shaking. Intensity depends, however, in a complicated way not only on ground accelerations but also on the periods and other features of seismic waves, the distance of the point from the source, and the local geological structure. Furthermore, it is distinct from magnitude, which is a measure of earthquake size specified by a seismograph reading (see below *Earthquake magnitude*).

A number of different intensity scales have been set up during the past century and applied to both current and ancient destructive earthquakes. For many years the most widely used was the 10-point scale devised by Michele Stefano de Rossi and François-Alphonse Forel in 1878. The scale now generally employed in North America is the Mercalli scale, as modified by Harry O. Wood and Frank Neumann in 1931, in which intensity is considered to be more uniformly graded. An abridged form of the modified Mercalli scale is provided below. Alternative scales have been developed in both Japan and Europe for local conditions. The European (MSK) scale of 12 grades is similar to the abridged version of the Mercalli.

Mercalli scale

Modified Mercalli Scale of Felt Intensity (1931; Abridged)

I. Not felt. Marginal and long-period effects of large earthquakes.

II. Felt by persons at rest, on upper floors, or otherwise favourably placed to sense tremors.

III. Felt indoors. Hanging objects swing. Vibrations like passing of light trucks. Duration can be estimated.

IV. Vibration like passing of heavy trucks (or sensation of a jolt like a heavy ball striking the walls). Standing motorcars rock. Windows, dishes, doors rattle. Glasses clink. Crockery clashes. In the upper range of IV, wooden walls and frames creak.

V. Felt outdoors; direction may be estimated. Sleepers wakened. Liquids disturbed, some spilled. Small objects displaced or upset. Doors swing, open, close. Pendulum clocks stop, start, change rate.

VI. Felt by all; many frightened and run outdoors. Persons walk unsteadily. Pictures fall off walls. Furniture moved or overturned. Weak plaster and masonry cracked. Small bells ring (church, school). Trees, bushes shaken.

VII. Difficult to stand. Noticed by drivers of motorcars. Hanging objects quiver. Furniture broken. Damage to weak masonry. Weak chimneys broken at roof line. Fall of plaster, loose bricks, stones, tiles, cornices. Waves on ponds; water turbid with mud. Small slides and caving along sand or gravel banks. Large bells ring. Concrete irrigation ditches damaged.

VIII. Steering of motorcars affected. Damage to masonry; partial collapse. Some damage to reinforced masonry; none to reinforced mansonry designed to resist lateral forces. Fall of stucco and some masonry walls. Twisting, fall of chimneys, factory stacks, monuments, towers, elevated tanks. Frame houses moved on foundations if not bolted down; loose panel walls thrown out. Decayed piling broken off. Branches broken from trees. Changes in flow or temperature of springs and wells. Cracks in wet ground and on steep slopes.

IX. General panic. Weak masonry destroyed; ordinary masonry heavily damaged, sometimes with complete collapse; reinforced masonry seriously damaged. Serious damage to reservoirs. Underground pipes broken. Conspicuous cracks in ground. In alluvial areas, sand and mud ejected, earthquake fountains, sand craters.

X. Most masonry and frame structures destroyed with their foundations. Some well-built wooden structures and bridges destroyed. Serious damage to dams, dikes, embankments. Large landslides. Water thrown on banks of canals, rivers, lakes, etc. Sand and mud shifted horizontally on beaches and flat land. Railway rails bent slightly.

XI. Rails bent greatly. Underground pipelines completely out of service.

XII. Damage nearly total. Large rock masses displaced. Lines of sight and level distorted. Objects thrown into air.

With the use of an intensity scale, it is possible to summarize the macroseismic data for an earthquake by constructing isoseismal curves, which are the loci of points that demarcate areas of equal intensity. If there were complete symmetry about the vertical through the earthquake's focus, the isoseismals would be circles with the epicentre as centre. However, because of the many unsymmetrical factors influencing the intensity, the curves are often far from circular.

The most probable position of the epicentre based on macroseismic data will be at a point inside the area of highest intensity. In some cases, it is verified by instrumental data that the epicentre is satisfactorily determined in this way, but not infrequently the true epicentre lies outside the area of greatest intensity.

Area of highest intensity

Tsunamis and seiches. *Tsunamis.* Very long water waves in oceans or seas, tsunamis (or seismic sea waves), sweep inshore following certain earthquakes. They sometimes reach great heights and may be extremely destructive. The immediate cause of a tsunami is a disturbance in an adjacent seabed sufficient to cause the sudden raising or lowering of a large body of water. This disturbance may be centred in the focal region of an earthquake or it may be a submarine landslide arising from an earthquake. Following the initial disturbance to the sea surface, water waves spread out in all directions. Their speed of travel in deep water is given by $(gh)^{1/2}$, where h is the sea depth and g is the acceleration of gravity. This speed may be considerable; *e.g.*, 100 metres per second (224 miles per hour) when h is 1,000 metres (3,280 feet). The amplitude at the surface does not exceed a few metres in deep water, but the principal wavelength may be on the order of hundreds of kilometres; correspondingly, the principal wave period may be on the order of tens of minutes. Because of these features, the waves are not noticed by ships far out at sea.

Speed of travel

When tsunamis approach shallow water, the wave amplitude increases. The waves may occasionally reach a height of 20 to 30 metres in U- and V-shaped harbours and inlets. They sometimes do a great deal of damage in low-lying ground around such inlets. Frequently the wave front in the inlet is nearly vertical, as, for example, in a tidal bore, and the speed of onrush may be on the order of 10 metres per second. In some cases there are several great waves separated by intervals of several minutes or more. The first of these waves is often preceded by an extraordinary recession of water from the shore, which may commence several minutes or even half an hour beforehand.

Organizations, notably in Japan, Siberia, Alaska, and Hawaii, have been set up to provide tsunami warnings. A key development is the Seismic Sea Wave Warning System (SSWWS), an internationally supported system designed to reduce loss of life in the Pacific Ocean. Centred in Honolulu, it issues alerts based on reports of earthquakes from circum-Pacific seismographic stations.

Seiches. These are rhythmic motions of water in nearly landlocked bays or lakes that are sometimes induced by earthquakes and by tsunamis (in the case of the former). Oscillations of this sort may last for hours or even for a day or two.

The great Lisbon earthquake of 1755 caused the waters of canals and lakes in areas as far away as Scotland and Sweden to go into observable oscillations. Seiche surges in Texas in the southwestern United States commenced between 30 and 40 minutes after the 1964 Alaska earthquake and were produced by seismic surface waves passing through the area.

Of course, *P* waves from an earthquake may pass through the sea following refraction through the seafloor. The speed of these waves is about 1.5 kilometres per second, the speed of sound in water. If such waves meet a ship with sufficient intensity, they give the impression that the ship has struck a submerged object. This phenomenon is called a seaquake.

Some great earthquakes. About 50,000 earthquakes large enough to be felt or noticed without the aid of instruments occur annually over the entire Earth. Of these, approximately 100 are of sufficient size to produce substantial damage if their centres are near areas of habitation. Very great earthquakes occur at an average rate of about one per year. Among the great earthquakes of the past are those of Lisbon in 1755; New Madrid, Mo., U.S., in December 1811 and January and February 1812; San Francisco in 1906; Tokyo–Yokohama in 1923; the coast of Chile in 1960; south-central Alaska in 1964; T'ang-shan, China, in 1976; and Mexico in 1985. Their devastating effects are briefly described below.

Lisbon. On Nov. 1, 1755, Lisbon was heavily damaged by a great earthquake that occurred at 9:40 AM. The source was situated some distance off the coast. The violent shaking demolished large public buildings and about 12,000 dwellings. As November 1 was All Saint's Day, a large part of the population was attending religious services; most of the churches were destroyed, resulting in many casualties. The total number of persons killed in Lisbon alone was estimated to be as high as 60,000, including those who perished by drowning and in the fire that burned for about six days following the shock. Damage was reported in Algiers, 1,100 kilometres to the east. The earthquake generated a tsunami that produced waves about six metres high at Lisbon and 20 metres high at Cádiz, Spain. The waves traveled on to Martinique, a distance of 6,100 kilometres in 10 hours, and there rose to a height of four metres.

New Madrid. Three large earthquakes occurred near New Madrid in southern Missouri on Dec. 16, 1811, and Jan. 23 and Feb. 7, 1812. There were numerous aftershocks, of which 1,874 were large enough to be felt in Louisville, Ky., some 300 kilometres away. The principal shock produced waves of sufficient amplitude to shake down chimneys in Cincinnati, Ohio, about 600 kilometres away. The waves were felt as far as Canada in the north and the Gulf Coast in the south. The area of greatest shaking was about 100,000 square kilometres, considerably greater than the area involved in the San Francisco earthquake in 1906. It has been discovered that in continental earthquakes such as the Missouri shocks, the area of strong shaking can be abnormally large compared with that in shocks along the Pacific coast of the United States. In one region 240 kilometres long by 60 kilometres wide, the ground sank from one to three metres and was covered by inflowing river water. Sand liquefaction effects were widespread. In certain locations, forests were overthrown or ruined by the loss of soil shaken from the roots of the trees.

San Francisco. On April 18, 1906, at about 5:12 AM, the San Andreas Fault slipped over a segment about 430 kilometres long, extending from San Juan Bautista in San Benito County to the upper Mattole River in Humboldt County and from there perhaps out under the sea to an unknown distance. The shaking was felt from Los Angeles in the south to Coos Bay, Ore., in the north. Damage was severe in San Francisco and in other towns situated near the fault—*e.g.,* San Jose, Salinas, and Santa Rosa (30 kilometres from the fault). Approximately 700 people were killed. In San Francisco the earthquake started a fire, which destroyed the central business district.

Tokyo–Yokohama. A great earthquake struck the Tokyo–Yokohama metropolitan area near noon on Sept. 1, 1923. The death toll from this shock was estimated at more than 140,000. Fifty-four percent of the brick buildings and 10 percent of the reinforced concrete structures collapsed. Many hundreds of thousands of houses were either shaken down or burned. The shock started a tsunami that reached a height of 12 metres at Atami on Sagaminada (Sagami Gulf), where it destroyed 155 houses and killed 60 persons.

Chile. The source of this earthquake in 1960 extended over a distance of about 1,100 kilometres along the southern Chilean coast. Casualties included about 5,700 killed and 3,000 injured, and property damage amounted to many millions of dollars. Seismic sea waves excited by the earthquake caused death and destruction in Hawaii, Japan, and the Pacific coast of the United States.

Alaska. On March 27, 1964, a great earthquake with a Richter magnitude 8.3–8.5 (see below) occurred in south central Alaska. It released at least twice as much energy as the 1906 San Francisco earthquake and was felt on land over an area of almost 1,300,000 square kilometres. The death toll was only 131 because of the low density of the state's population, but property damage was very high. The earthquake tilted an area of at least 120,000 square kilometres. Landmasses were thrust up locally as high as 25 metres to the east of a line extending northeastward from Kodiak Island through the western part of Prince William Sound. To the west, land sank as much as 2.5 metres. Extensive damage in coastal areas resulted from submarine landslides and tsunamis. Tsunami damage occurred as far away as Crescent City, Calif. The occurrence of tens of thousands of aftershocks indicates that the region of faulting extended about 1,000 kilometres.

T'ang-shan. The coal-mining and industrial city of T'ang-shan, located about 110 kilometres east of Peking, was almost razed in the tragic earthquake of July 28, 1976. The death toll exceeded 240,000 persons, and probably another 500,000 were injured. Most persons were killed from the collapse of unreinforced masonry homes, where they were asleep.

Mexico. The main shock occurred at 7:18 AM on Sept. 19, 1985. The cause was a fault slip along the Benioff zone (a band of intermediate- and deep-earthquake foci along a planar dipping zone) under the Pacific coast of Mexico. Although 400 kilometres from the epicentre, Mexico City suffered major building damage and more than 10,000 of its inhabitants were reported killed. The highest intensity was in the central city, which is founded on a former lake bed. The ground motion there measured five times that in the outlying districts, which have different soil foundations.

CAUSES OF EARTHQUAKES

Principal mechanisms in nature. Earthquakes are caused by the sudden release of energy within some limited region of the rocks of the Earth. The form of energy involved is produced by elastic strain, gravitational potential, chemical reactions, or motion of bodies. Of these, the release of elastic strain energy is the most important, since this form of energy is the only kind that is stored in sufficient quantity in the Earth to produce major earthquakes. Earthquakes associated with this type of energy release are called tectonic earthquakes.

Measurements of triangulation lines across the San Andreas Fault before and after its rupture in the 1906 San Francisco earthquake led to the so-called elastic rebound theory for tectonic earthquakes. As formulated by the American geologist Harry Fielding Reid, the theory ex-

Elastic rebound theory

plains that a tectonic earthquake occurs when stresses in rock masses have accumulated to a point where they exceed the strength of the rocks, leading to rapid fracture. These rock fractures usually tend in the same direction and may extend over many kilometres along the zone of weakness. In the 1906 earthquake the San Andreas Fault slipped for 430 kilometres, with a maximum horizontal fault offset of about six metres.

Another type of earthquake, that associated with volcanic activity, is called a volcanic earthquake. Yet, it is likely that even here the energy released may be the result of a relatively sudden slip of rock masses and the consequent release of elastic strain energy. The energy, however, may in part be of hydrodynamic origin due to the motion of magma in reservoirs beneath the volcano or to the release of gas under pressure.

The elastic rebound theory of an earthquake source envisages the flinging of rock masses in opposite directions on each side of the rupturing fault as the fault rupture progresses along the fault. In the rupture, the rock masses spring back to a position where the elastic strain is less. This movement at any point may not take place at once but rather in irregular steps. These sudden stoppings and startings give rise to the vibrations that propagate as seismic waves. The irregular properties of fault rupture are now included in the modeling of earthquake sources, both physically and mathematically. Roughnesses along the fault are referred to as asperities, and places where the rupture slows or stops are said to be fault barriers. Fault rupture starts at the earthquake focus and propagates unilaterally or bilaterally over the fault plane until stopped or slowed at a barrier. The result is a redistribution of elastic strain, which may or may not break the barrier. Sometimes the fault rupture is reinstated on the far side of the barrier; sometimes the stresses in the rocks eventually produce a breakage, and the rupture continues.

Earthquakes have different properties depending on the type of fault slip that causes them. The geological interpretation of a fault is given in terms of standard geometries (Figure 2). The usual fault model has a strike (direction from north of the horizontal line in the fault plane) and a dip (angle between direction of steepest slope and horizontal). The hanging wall lies over the footwall, the lower wall of an inclined fault.

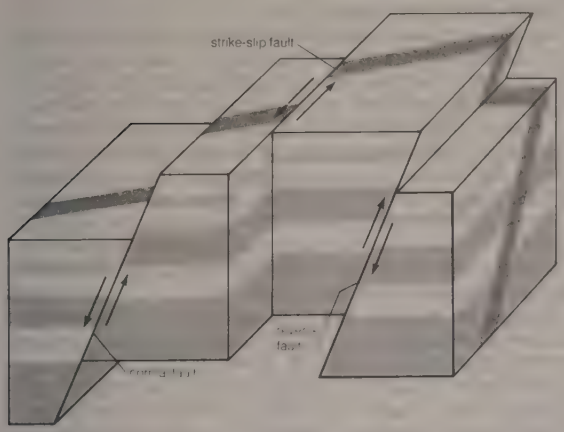

Figure 2: Types of faulting.

Types of fault movement

Relative offsets parallel to the strike produce strike-slip faulting while those parallel to the dip generate dip-slip faulting. Strike-slip faults are right or left lateral, depending on whether the block on the opposite side of the fault from the observer moves to his right or left. Dip-slip faults are normal if the hanging-wall block moves downward relative to the footwall block; the opposite motion produces reverse or thrust faulting. A mixed offset results in oblique-slip faulting, which is measured either by the plunge or by the slip angle.

Observed faults are assumed to be the seat of one or more past earthquakes, though movements along faults are often slow, and most geologically ancient faults are now aseismic (*i.e.*, cause no earthquakes). The actual faulting in an earthquake may be complex, and it is often not clear whether in a particular earthquake the total energy issues from a single fault plane.

Observed geological faults sometimes show overall relative displacements on the order of hundreds of kilometres, whereas the amplitudes of seismic waves reach only several centimetres. In the 1976 T'ang-shan earthquake, for example, a surface strike-slip of about one metre was observed along the causative fault.

Polarity method

An important research technique is to infer the character of faulting in an earthquake from observed distributions of the directions of the first onsets in waves arriving at the Earth's surface. Onsets have been called compressional or dilatational according to whether the direction is away from or toward the focus, respectively. A polarity pattern becomes recognizable when the directions of the *P*-wave onsets are plotted on a map: there are broad areas in which the first onsets are predominantly compressions, separated from predominantly dilatational areas by nodal curves near which the *P*-wave amplitudes are abnormally small.

In 1926 the American geophysicist Perry E. Byerly used patterns of *P* onsets over the entire globe to infer the orientation of the fault plane in a large earthquake. The polarity method yields two *P*-nodal curves at the Earth's surface. For a homogeneous Earth, one curve is in the plane containing the assumed fault, and the other is in the plane (called the auxiliary plane) that passes through the focus and is perpendicular to the forces of the plane. For the actual Earth, the nodal curves are displaced from these locations because of the curvature of the wave paths between focus and surface, but knowledge of Earth structure enables allowance to be made for this. Given an adequately well-determined pattern of first *P*-wave movements, it is possible to locate two planes, one of which is the plane containing the fault.

Artificial means of inducing earthquakes. Earthquakes are sometimes caused by human activities. Such activities include the injection of fluids into deep wells, the detonation of large underground nuclear explosions, the excavation of mines, and the filling of large reservoirs. In the case of deep mining, the removal of rock produces changes in the strain around the tunnels. Slip on preexisting faults or outward shattering of rock into the cavities may occur. In all other situations, the induction mechanism is thought to involve elastic strain release, as in the case of tectonic earthquakes. Here, earthquakes are triggered by small changes in the local strain field that produce rock fracture or fault slip. Local changes in strain around large underground explosions have been known to produce slip on already strained faults in the vicinity.

Reservoir induction. Of the various activities cited above, the filling of large reservoirs is among the most important. More than 20 cases have been documented in which local seismicity has increased following the impounding of water behind high dams. Other claims cannot be substantiated because the necessary observations that allow comparison of earthquake occurrence before and after filling do not exist. Reservoir-induction effects are most marked for reservoirs exceeding 100 metres in depth and one cubic kilometre in volume. Three cases where such effects have very probably been involved are the Hoover Dam in the United States, the Aswān High Dam in Egypt, and the Kariba Dam on the border between Zimbabwe and Zambia. The most generally accepted explanation for the cause of the earthquake occurrence in such cases is that rocks near the reservoir are already strained from the regional tectonic forces to a point where nearby faults are almost ready to slip. Water in the reservoir adds a pressure perturbation that triggers the fault rupture. The pressure effect perhaps is enhanced by the fact that the rocks along the fault have lower strength due to increased water-pore pressure. These factors notwithstanding, it has been determined that most large reservoirs do not produce earthquakes.

The specific earthquake mechanisms associated with reservoir induction have been established in a few cases. For the main shock at the Koyna Dam and Reservoir in India, the evidence favours strike-slip motion, and at Hsinfeng-chiang Dam in China, the principal shock can also be

attributed to the strike-slip mechanism. At both the Kremasta Dam in Greece and the Kariba Dam in Zimbabwe–Zambia, the mechanism was dip-slip on normal faults. By contrast, thrust mechanisms have been determined for earthquakes at the lake behind Nurek Dam in the Soviet Union. More than 1,800 earthquakes occurred during the first nine years after water was impounded in this 317-metre deep reservoir, a rate amounting to four times the average number of shocks in the region prior to filling.

Seismology and nuclear explosions. In 1958 representatives from several countries, including the United States and the Soviet Union, met to discuss the technical basis for a nuclear test ban treaty. Among the matters considered was the feasibility of developing effective means with which to detect underground nuclear explosions and to distinguish them seismically from earthquakes. Since that conference, much attention has been devoted to seismological research, leading to major advances in seismic signal detection and analysis in terms of both instrumentation and methodology.

Stimulus for seismological research

Recent seismological work on test ban treaty verification has involved using high-resolution seismographs, estimating the yield of explosions, studying wave attenuation in the Earth, determining wave amplitude and frequency spectra discriminants, and applying seismic arrays (see above). The findings of such research have shown that underground nuclear explosions, compared with natural earthquakes, usually generate larger amplitude *P* waves relative to the surface waves. The extension of seismic explosion research (and the experimental controls that go with it) to seismological problems has yielded useful information on seismic wave propagation in general and on the Earth's structure.

DISTRIBUTION OF EARTHQUAKES

Earthquake observatories. During the late 1950s there existed worldwide only about 700 seismographic stations equipped with seismographs of various types and frequency responses. Few instruments were calibrated, so that actual ground motions could not be measured and timing errors of several seconds were common. The WWSSN, the aforementioned worldwide standardized seismographic network, was established to help remedy this situation. Each station of the WWSSN has six seismographs—three short-period and three long-period seismographs. Timing and accuracy are maintained by crystal clocks, and a calibration pulse is placed daily on each record. By 1967 the WWSSN consisted of about 120 stations distributed over 60 countries. Other countries, such as Canada, which did not participate directly in the WWSSN, upgraded their own stations in order to make them compatible with the standardized network. The resulting data provided the basis for significant advances in research on earthquake mechanisms, global tectonics, and the structure of the Earth's interior.

By the 1980s a further upgrading of permanent seismographic stations had begun with the installation of digital equipment. Among the global networks of digital seismographic stations now in operation are the seismic research observatories in boreholes 100 metres deep; modified high-gain, long-period (surface) observatories; and digital worldwide standardized seismographic network (DWWSSN) stations. In addition, a number of gravimeters capable of digital recording and response to very long wavelengths have been installed throughout the world as part of the International Deployment of Accelerographs (IDA) network. The main aim is to equip global observatories with seismographs that can record seismic waves over a broad band of frequencies.

Networks of digital seismographic stations

Locating earthquake epicentres. At some observatories it is customary to make provisional estimates of the epicentres of the more important earthquakes. These estimates provide preliminary information locally about particular earthquakes and serve as first approximations for the calculations subsequently made by large coordinating centres. (Distances between stations and an earthquake epicentre are calculated in terms of the angle subtended at the Earth's centre; Figure 5.)

In the case of a single observatory, an earthquake's epicentre can often be estimated from the readings of three perpendicular component seismograms. For example, for a shallow earthquake the epicentral distance, if less than 105°, is indicated by the interval between the arrival times of *P* and *S* waves; the azimuth and angle of emergence are indicated by a comparison of the sizes and directions of the first movements shown in the seismograms and by the relative sizes of later waves, particularly surface waves. It should be noted, however, that in certain regions the first wave movement at a station arrives from a direction differing from the azimuth toward the epicentre. The explanation is usually in terms of strong variations in geological structures.

When data from more than one observatory are available, an earthquake's epicentre may be estimated from the epicentral distances indicated by the times of travel of the *P* and *S* waves from source to recorder. Nowadays, in many seismically active regions, networks of seismographs with telemetry transmission and centralized timing and recording are common. Whether analog or digital recording is used, such integrated systems greatly simplify observatory work: multichannel signal displays make identification and timing of phase onsets easier and more reliable.

Moreover, modern on-line microprocessors can be programmed to pick automatically, with some degree of confidence, the onset of a significant common phase, such as *P*, by correlation of waveforms from parallel network channels. With the aid of specially designed computer programs, seismologists can then locate distant earthquakes to within about 10 kilometres and the epicentre of a local earthquake to within just a few kilometres.

Cataloging of earthquakes

Catalogs of felt earthquakes and earthquake observations have appeared intermittently for many centuries. The earliest known list of instrumentally recorded earthquakes with computed times of origin and epicentres is that for the period 1899–1903. In subsequent years, cataloging of earthquakes has become increasingly more uniform and complete. Especially valuable is the service provided by the International Seismological Centre (ISC) at Newbury, Eng. Each month it receives about 80,000 readings from about 1,200 stations worldwide and preliminary estimates of the locations of approximately 1,600 earthquakes from national and regional agencies and observatories. The ISC publishes montly, with about a two-year delay, a bulletin that provides all available information on each of about 1,500 to 2,000 earthquakes.

Various national and regional centres control networks of stations and act as intermediaries between individual stations and the international organizations. Examples of long-standing national centres include the Japan Meteorological Agency and the Canadian Seismograph Network operated by the Department of Energy, Mines and Resources of Ottawa. These centres normally make estimates of the magnitudes, epicentres, origin times, and focal depths of local earthquakes. Of particular importance is the U.S. National Earthquake Information Service in Colorado, which can make rapid determinations of earthquake locations anywhere in the world.

Geographic concentrations of earthquakes. The Earth's major earthquakes occur mainly in belts coinciding with the margins of tectonic plates (see below). This has long been apparent from early catalogs of felt earthquakes and is even more readily discernible in modern seismicity maps, such as the one given in Figure 3, which show instrumentally determined epicentres.

Major earthquake belts

One major earthquake belt passes around the Pacific Ocean and affects coastlines bordering on it, as, for example, those of New Zealand, New Guinea, Japan, the Aleutian Islands, Alaska, and the western regions of North and South America. It is estimated that 80 percent of the energy presently released in earthquakes comes from those whose epicentres are in this belt. The seismic activity is by no means uniform throughout the belt, and there are a number of branches at various points.

A second belt passes through the Mediterranean region eastward through Asia and joins the first belt in the East Indies. The energy released in earthquakes from this belt is about 15 percent of the world total. There also are striking connected belts of seismic activity, mainly along

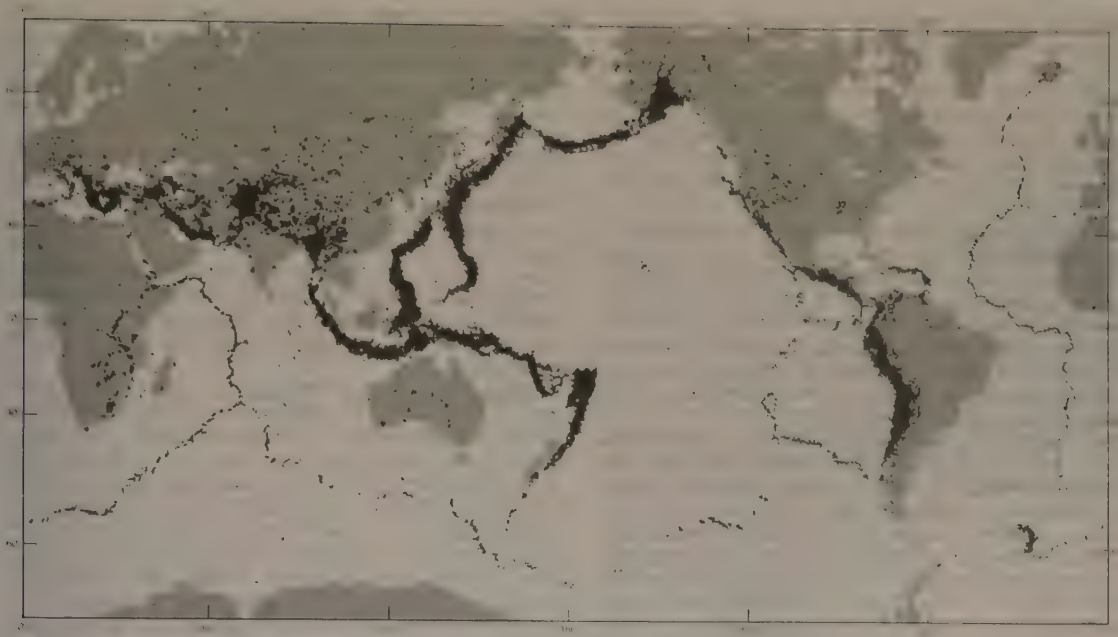

Figure 3: Distribution of earthquake epicentres (black areas), 1963–77.

mid-oceanic ridges—including those in the Arctic Ocean, the Atlantic Ocean, and the western Indian Ocean—and along the rift valleys of East Africa.

Most other parts of the world experience at least occasional shallow earthquakes—those that originate within 60 kilometres of the Earth's outer surface. The great majority of earthquakes are shallow. It should be noted that the geographic distribution of smaller earthquakes is less precisely determined, partly because the availability of relevant data is dependent on the geographical distribution of observatories.

A distinction is made between "intermediate" focal depths ranging from about 60 to 300 kilometres and greater focal depths. Of the total energy released in earthquakes, 12 percent comes from intermediate earthquakes and 3 percent from deeper ones. The frequency of occurrence falls off rapidly with increasing focal depth in the intermediate range, while below this the distribution in depth is fairly uniform until the greatest focal depths are approached.

Concentrations of deep-focus earthquakes

Deep-focus earthquakes commonly occur in patterns called Benioff zones that dip into the Earth. Dip angles average about 45°, with some shallower and others nearly vertical. Benioff zones are found under tectonically active island arcs, such as Japan, Vanuatu (formerly the New Hebrides), the Kingdom of Tonga (islands), and Alaska, and they are normally but not always (*e.g.*, Romania and the Hindu Kush mountain system) associated with deep ocean trenches, such as those along the South American Andes. In most Benioff zones intermediate- and deep-earthquake foci lie in a narrow layer, although recent precise hypocentral locations in Japan and elsewhere show two distinct parallel bands of foci 20 kilometres apart. Careful estimation gives about 680 kilometres for the deepest depths globally.

Tectonic associations. There is a clear correspondence between the geographical distribution of volcanoes and major earthquakes, particularly in the circum-Pacific earthquake belts and along mid-oceanic ridges. Volcanic vents, however, are generally at a distance of some hundreds of kilometres from the majority of the epicentres of major shallow earthquakes, and many earthquake sources occur nowhere near active volcanoes. Earthquakes of intermediate focal depth frequently occur directly below structures marked by volcanic vents, but there is probably no immediate causal connection between these earthquakes and the volcanic activity, both most likely resulting from the same tectonic processes.

Seismicity patterns had no strong global theoretical explanation until a dynamical model called plate tectonics was developed during the late 1960s. This theory holds that the Earth's upper shell, or lithosphere, consists of nearly a dozen large, quasi-stable slabs called plates. The thickness of each of these plates extends to a depth of roughly 80 kilometres. The plates move horizontally, relative to neighbouring plates, on a layer of softer rock. The rate of movement ranges from one to 10 centimetres per year over a shell of lesser strength called the asthenosphere. At the plate edges where there is contact with adjoining plates, boundary tectonic forces operate on the rocks, causing physical and chemical changes in them. New lithosphere is created at mid-oceanic ridges by the upwelling and cooling of magma from the Earth's mantle. The horizontally moving plates are believed to be absorbed at the ocean trenches, where a subduction process carries the lithosphere downward along the Benioff zones into the Earth's interior. The total amount of lithospheric material destroyed at these subduction zones equals that generated at the ridges.

High seismicity along plate boundaries

Seismological evidence (*e.g.*, location of major earthquake belts, as shown in Figure 3) is broadly in agreement with this kinematic model. Earthquake sources are concentrated along the midoceanic ridges, which correspond to divergent plate boundaries. At the subduction zones, which are associated with convergent plate boundaries, intermediate- and deep-focus earthquakes in the Benioff zone mark the location of the upper part of a dipping plate. The focal mechanisms indicate that the stresses are aligned with the dip of the lithosphere underneath the adjacent continent or island arc.

Some earthquakes associated with mid-oceanic ridges are confined to strike-slip faults that offset the ridge crests. The majority of the earthquakes occurring along such horizontal shear faults are characterized by slip motions. Also consistent with the plate tectonics theory is the high seismicity encountered along the edges of plates that slide past each other. Examples of plate boundaries of this kind, which are sometimes called fracture zones, include the San Andreas Fault in California and the North Anatolian fault system in Turkey. Such plate boundaries are the site of interplate earthquakes of shallow focus.

One other point that correlates with the plate theory is the low seismicity within plates. Small to large earthquakes do occur in limited regions well within the boundaries of plates; however, such interplate seismic events must be explained by mechanisms other than plate motions and their associated phenomena. (See PLATE TECTONICS for further information.)

Aftershocks, foreshocks, and swarms. Usually a major or even moderate earthquake of shallow focus is followed by many lesser earthquakes close to the original source

region. This is to be expected because the fault rupture producing a major earthquake does not relieve all of the accumulated strain energy at once. Furthermore, this dislocation is liable to cause an increase in the stress and strain at a number of places in the vicinity of the focal region, bringing crustal rocks at certain points close to the stress at which fracture occurs. In some cases the frequency of aftershocks may be for a time as high as 1,000 or more a day.

Sometimes a large earthquake is followed by another at approximately the same focus within an hour or perhaps a day. An extreme case of this is multiple earthquakes. In most instances, however, the first principal earthquake of a series is much more energetic than the aftershocks. In general, the number of aftershocks per day decreases with increasing time. The aftershock frequency is roughly inversely proportional to the time since the occurrence of the largest earthquake of the series.

Aftershock frequency

Most major earthquakes occur without detectable warning from less energetic precursor earthquakes, but some principal earthquakes are preceded by foreshocks. In another pattern of occurrence, large numbers of small earthquakes occur in a region over an interval of time that may extend to some months without a major earthquake occurring. In the Matsushiro region of Japan, for instance, there occurred between August 1965 and 1967 a series of hundreds of thousands of earthquakes, some sufficiently strong (up to local magnitude 5) to cause property damage but no casualties. The maximum frequency was 6,780 small earthquakes on April 17, 1966. Such series of earthquakes are called earthquake swarms. Earthquakes associated with volcanic activity often occur in swarms, but swarms also have been observed in many nonvolcanic regions.

Extraterrestrial seismic phenomena. Space vehicles have carried equipment to the surface of the Moon and Mars with which to record seismic waves, and seismologists on Earth have received telemetered signals from seismic events in both cases.

By 1969 seismographs had been placed at six sites on the Moon during the U.S. Apollo missions. Recording of seismic data ceased in September 1977. The instruments detected between 600 and 3,000 moonquakes during each year of their operation, though most of these seismic events were very small. The ground noise on the lunar surface is low compared with that of the Earth so that the seismographs could be operated at very high magnifications. Because there was more than one station on the Moon, it was possible to use the arrival times of *P* and *S* waves at the lunar stations from the moonquakes to determine foci in the same way as is done on the Earth.

Causes of moonquakes

Moonquakes are of three types. First, there are the events caused by the impact of lunar modules, booster rockets, and meteorites. The lunar seismograph stations were able to detect meteorites hitting the Moon's surface more than 1,000 kilometres away. The two other types of moonquakes had natural sources in the Moon's interior: they presumably resulted from rock fracturing, as on Earth. The most common type of natural moonquake had deep foci, at depths of 600 to 1,000 kilometres; the less common variety had shallow focal depths.

Seismological research on Mars has been less successful. Only one of the seismometers carried to the Martian surface by the U.S. Viking landers during the mid-1970s remained operational. Perhaps only one marsquake was detected in 546 Martian days.

SIZE, ENERGY, AND FREQUENCY OF EARTHQUAKES

Microseisms

As noted earlier, small ground motions known as microseisms are commonly recorded by seismographs. These weak wave motions are not generated by earthquakes, and they complicate accurate recording of the latter. They, however, are of scientific interest because their form is related to the Earth's surface structure.

Some microseisms have local causes, as, for example, those due either to traffic or machinery, or to local wind effects and storms. Another class of microseisms exhibits features that are very similar to those on records traced at earthquake observatories distributed over a wide area. The features include approximately simultaneous occurrence of maximum amplitudes and similar wave frequencies at all the observatories concerned. These microseisms may persist for many hours and have more or less regular periods of about five to eight seconds. The largest amplitudes of such microseisms are on the order of 10^{-3} centimetres and occur in coastal regions. The amplitudes also depend to some extent on local geological structure. There is a fair correlation between the size of microseisms and the occurrence of stormy weather conditions in some adjacent region.

Some microseisms are generated by the action of rough surf against an extended steep coast, while others are produced when large standing water waves are formed at sea. The period of the latter type of microseism is half that of the standing wave.

Earthquake magnitude. Because the size of earthquakes varies enormously it is necessary for purposes of relative comparison to compress the range of wave amplitudes measured on seismograms by means of a mathematical device. In 1935 the American seismologist Charles F. Richter set up a "magnitude scale of earthquakes" as the logarithm to base 10 of the maximum seismic wave amplitude (in thousandths of a millimetre) recorded on a standard seismograph (the Wood–Anderson torsion pendulum seismograph) at a distance of 100 kilometres from the earthquake epicentre. Reduction of amplitudes observed at various distances to the amplitudes expected at the standard distance of 100 kilometres is made on the basis of empirical tables. Richter magnitudes M_L are computed on the assumption that the ratio of the maximum wave amplitudes at two given distances is the same for all earthquakes considered and is independent of azimuth.

Richter magnitude scale

Richter first applied his magnitude scale to shallow-focus earthquakes recorded within 600 kilometres of the epicentre in the southern California region. Later, additional empirical tables were set up, whereby observations made at distant stations and on seismographs other than the standard type could be used. Empirical tables were extended to cover earthquakes of all significant focal depths and to enable independent magnitude estimates to be made from body- and surface-wave observations.

At the present time, a number of different magnitude scales are used by scientists and engineers as a measure of the relative size of an earthquake. The *P*-wave magnitude (m_b), for one, is defined in terms of the amplitude of the *P* wave recorded on a standard seismograph. Similarly, the surface-wave magnitude (M_s) is defined in terms of the logarithm of the maximum amplitude of the ground motion for surface waves with a wave period of 20 seconds.

Taken as such, a magnitude scale has no lower or upper limit. Sensitive seismographs can record earthquakes with magnitudes of negative value and have recorded magnitudes up to about 9.0. (The 1906 San Francisco earthquake, for example, had a Richter magnitude of 8.25.)

There is, in effect, no direct mechanical basis for magnitude. Rather, it is an empirical parameter analogous to stellar magnitude. In modern practice, a more soundly based mechanical measure of earthquake size is used—namely, the seismic moment (M_0). Such a parameter is related to the angular leverage of the forces that produce the slip on the causative fault. It can be calculated both from recorded seismic waves and from field measurements of the size of the fault rupture. Consequently, seismic moment provides a more uniform scale of earthquake size. Still another magnitude currently in use is called moment magnitude (M_w). It is proportional to the logarithm of the seismic moment. Given the above definitions, the great Alaska earthquake of 1964 had the values $M_s = 8.4$, $M_0 = 820 \times 10^{27}$ dyne centimetres, $M_w = 9.2$.

Seismic moment as a measure of earthquake size

Energy and frequency of occurrence. Energy in an earthquake passing a particular surface site can be calculated directly from the recordings of strong ground motion, which is given as ground velocity. Such recordings indicate an energy rate of 10^5 watts per square metre near a moderate-sized earthquake source. The total power output of a rupturing fault in a shallow earthquake is on the order of 10^{14} watts compared with the 10^5 watts generated in rocket motors.

The magnitude M_s has also been connected with the energy E_s of an earthquake by empirical formulas. These give $E_s = 6.3 \times 10^{11}$ and 1.4×10^{25} ergs for earthquakes of $M_s = 0$ and 8.9, respectively. A unit increase in M_s thus corresponds to a 32-fold increase in energy. Negative magnitudes correspond to the smallest instrumentally recorded earthquakes, a magnitude of 1.5 to the smallest felt earthquakes and one of 3 to any shock felt at a distance of up to 20 kilometres. Earthquakes of magnitude 5.0 cause light damage near the epicentre; those of 6 are destructive over a restricted area; and those of 7.5 are at the lower limit of major earthquakes.

Total annual energy output

The total annual energy released in all earthquakes is about 10^{25} ergs, corresponding to a rate of work between 10,000,000 and 100,000,000 kilowatts. This is on the order of 0.001 of the annual amount of heat escaping from the Earth's interior. Ninety percent of the total seismic energy comes from earthquakes of magnitude 7.0 and higher—*i.e.*, those whose energy is on the order of 10^{23} ergs or more.

There also are empirical relations for the frequencies of earthquakes of various magnitudes. Suppose N to be the average number of shocks per year for which the magnitude lies in the range $M_s \pm \Delta M_s$. Then $\log_{10} N = a - bM_s$ fits the data well both globally and for particular regions; *e.g.*, for shallow earthquakes worldwide: $a = 6.7$, $b = 0.9$ when $M_s > 6.0$. The frequency for larger earthquakes therefore increases by a factor of about 10 when the magnitude is diminished by one unit. The increase in frequency with reduction in M_s falls short, however, of matching the decrease in the energy E. Thus larger earthquakes are overwhelmingly responsible for most of the total seismic energy release. The number of earthquakes per year with $m_b > 4.0$ may reach 20,000.

EARTHQUAKE PREDICTION

Observation and interpretation of precursory phenomena. The search for periodic cycles in earthquake occurrence is an old one. Generally, periodicities in time and space for major earthquakes have not been widely detected or accepted. One problem is that earthquake catalogs are not homogeneous in their selection and reporting. The most extensive catalog of this kind comes from China and begins about 700 BC. The catalog contains some information about 1,000 destructive earthquakes. The sizes of these earthquakes have been assessed from the reports of damage, intensity, and shaking.

Another approach to the statistical occurrence of earthquakes involves the postulation of trigger forces that initiate the rupture. Such forces have been attributed, for example, to severe weather conditions, volcanic activity, and tidal forces. Usually correlations are made between the physical phenomena assumed to provide the trigger and the repetition of earthquakes. Inquiry must always be made to discover whether a causative link is actually present. No trigger mechanism, at least for moderate to large earthquakes, has been found that satisfies the various criteria necessary to establish a clear physical connection.

Statistical methods also have been tried with populations of regional earthquakes. It has been suggested that the slope b of the regression line between the number of earthquakes and the magnitude, mentioned in the previous section, for a region may change characteristically with time. Specifically, the b value for the population of foreshocks of a major earthquake may be significantly smaller than the mean b value for the region averaged over a long interval of time.

For prediction of the time of earthquake occurrence, a proposal is that precursory changes in a region will cause the velocity of seismic waves through the region to change. Thus, if appropriate travel-time residuals are plotted as a function of time, fluctuations will provide a forewarning.

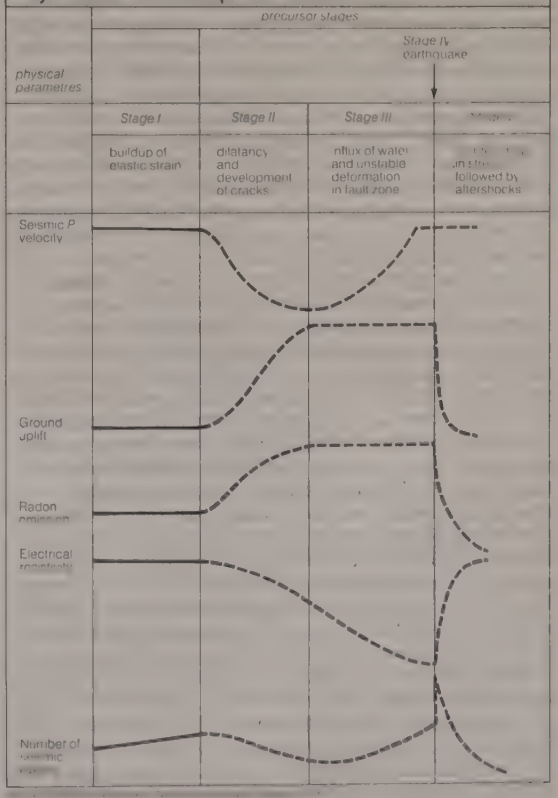
The elastic rebound theory for the occurrence of earthquakes described earlier allows rough prediction of large shallow earthquakes. H.F. Reid gave, for example, a crude forecast of the next great earthquake near San Francisco. (The theory also predicted of course that the place would be along the San Andreas or an associated fault.) The geodetic data indicated that during an interval of 50 years relative displacements of 3.2 metres had occurred at distant points across the fault. The maximum elastic-rebound offset along the fault in the 1906 earthquake was 6.5 metres. Therefore, $(6.5/3.2) \times 50$, or about 100 years, would again elapse before sufficient strain accumulated for the occurrence of an earthquake comparable to that of 1906. The premises are that the regional strain will grow uniformly and that various constraints have not been altered by the great 1906 rupture itself (*e.g.*, by the onset of slow fault slip).

For many years prediction research has been influenced by the basic argument that strain accumulates in the rock masses in the vicinity of a fault and results in crustal deformation. Deformations have been measured in the horizontal direction along active faults (by trilateration and triangulation) and in the vertical direction by precise leveling and tiltmeters. Some investigators believe that changes in groundwater level occur prior to earthquakes; variations of this sort have been reported mainly from China. It should be noted that water levels in wells respond to a complex array of factors such as rainfall; thus, if changes in water level are to be studied in relation to earthquakes, such factors need to be removed.

The theory of dilatancy of rock prior to rupture occupies a central position in recent discussions of premonitory phenomena of earthquakes. It is based on the observation that many solids exhibit dilatancy (*i.e.*, an increase in volume) during deformation. For earthquake prediction, the significance of dilatancy is its effects on various measurable quantities of the Earth's crust, such as seismic velocities, electric resistivity, and ground and water levels. The consequences of dilatancy for earthquake prediction are summarized in the Table. The best studied consequence is the effect on the seismic velocities. The influence of internal cracks and pores on the elastic properties of rocks can be clearly demonstrated in laboratory measurements of those properties as a function of hydrostatic pressure. In the case of saturated rocks, experiments predict—for shallow earthquakes—that dilatancy occurs as a portion of the crust is stressed to failure, causing a decrease in the velocities of seismic waves. Recovery of velocity is brought about by subsequent rise of pore pressure of water. The

Importance of dilatancy for earthquake prediction

Physical Clues for Earthquake Prediction



rise of pore pressure also has the effect of weakening the rock and enhancing fault slip.

Strain buildup in the focal region may have significant effects on other observable properties, including electrical conductivity and gas concentration. Because the electrical conductivity of rocks depends largely on interconnected water channels within the rocks, resistivity may increase before the cracks become saturated. As pore fluid is expelled from the closing cracks, the local water table would rise and concentrations of gases such as radioactive radon would increase.

Geological methods of extending the seismicity record back from the present also are being explored. Field studies indicate that the sequence of surface ruptures along major active faults associated with large earthquakes can sometimes be constructed. Liquefaction effects preserved in beds of sand and peat may provide evidence—when radiometric dating methods are used—for large "paleoearthquakes" extending back for more than 1,000 years.

Less well-grounded precursory phenomena, particularly earthquake lights and animal behaviour, sometimes draw more public attention than those discussed above. Many reports of unusual lights in the sky and abnormal animal behaviour preceding earthquakes are known to seismologists, mostly in anecdotal form. Both these phenomena are usually explained in terms of a release of gases prior to earthquakes and electric and acoustic stimuli of various types. At present there is no definitive experimental evidence to support claims that animals sometimes sense the coming of an earthquake.

Methods of reducing earthquake hazards. Considerable work has been done in seismology to explain the characteristics of the recorded ground motions in earthquakes. Such knowledge is needed to predict ground motions in future earthquakes so that earthquake-resistant structures can be designed. Although earthquakes cause death and destruction through such secondary effects as landslides, tsunamis, fires, and fault rupture, the greatest losses—both in lives and property—result from the collapse of man-made surface and subsurface structures during the violent shaking of the ground. Accordingly, the most effective way to mitigate the destructiveness of earthquakes from an engineering standpoint is to design and construct structures capable of withstanding strong ground motions.

Most elastic waves recorded close to an extended fault source are complicated and difficult to interpret uniquely. Understanding such near-source motion can be viewed as a three-part problem. The first part stems from the generation of elastic waves by the slipping fault as the moving rupture sweeps out an area of slip along the fault plane within a given time. The pattern of waves produced is dependent on a finite number of parameters, such as fault dimension and rupture velocity. Elastic waves of various types radiate from the vicinity of the moving rupture in all directions. The geometry and frictional properties of the fault critically affect the pattern of radiation from it.

The second part of the problem concerns the passage of the waves through the intervening rocks to the site and the effect of geological studies. The third part involves the conditions at the recording site itself, such as topography and highly attenuating soils. All these questions must be considered when an evaluation is being made of likely earthquake effects at a site of any proposed structure.

Experience has shown that accelerograms have a variable pattern in detail, but most have regular shapes in general (except in the case of strongly multiple earthquakes). An example of strong horizontal shaking of the ground (acceleration, velocity, and displacement) recorded during an actual earthquake is given in Figure 4. There is an initial segment of motion made up mainly of *P* waves, which frequently manifest themselves strongly in the vertical motion. This is followed by the onset of *S* waves, often associated with a longer period pulse related to the near-site fault slip or fling. After the *S* onset there is enhanced shaking that consists of a mixture of *S* and *P* waves, but the *S* motions become dominant as the duration increases. Later, in the horizontal component, surface waves dominate, mixed with some *S*-body waves. Depending on the distance of the site from the fault and the structure of the intervening rocks and soils, surface waves are spread out into long trains.

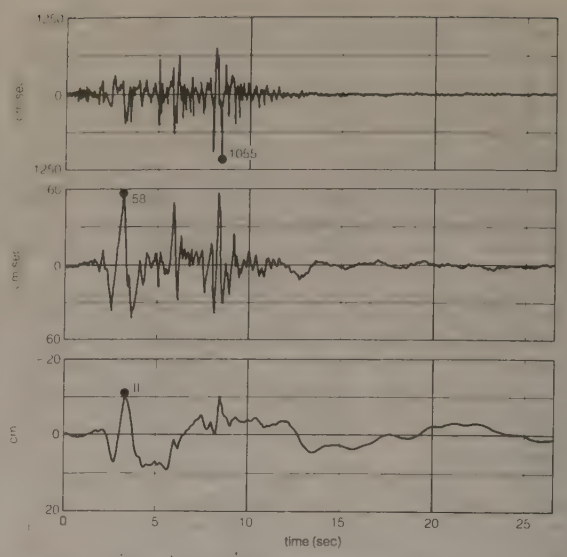


Figure 4: Recording of the San Fernando earthquake, near Pacoima Dam, California, 1971, showing (top) ground acceleration, (centre) velocity, and (bottom) displacement.

Earthquake risk maps

In many areas seismic expectancy maps or risk maps are now available for planning purposes. The anticipated intensity of ground shaking is represented by a number called the effective peak acceleration (EPA).

In order to avoid weaknesses found in earlier earthquake risk maps, the following general principles are usually adopted today: (1) the map should take into account not only the size but also the frequency of earthquakes; (2) the broad regionalization pattern should use as a data base historical seismicity, major tectonic trends, acceleration attenuation curves, and intensity reports; (3) regionalization should be defined by means of contour lines with design parameters referred to ordered numbers on neighbouring contour lines (this procedure minimizes sensitivity concerning the exact location of boundary lines between separate zones); (4) the map should be simple and not attempt to microzone the region; and (5) the mapped contoured surface should not contain discontinuities, so that the level of hazard progresses gradually and in order across any profile drawn on the map.

Developing structural designs that are able to resist the forces generated by seismic waves can be achieved either by following building codes based on risk maps or by appropriate methods of analysis. Many countries reserve theoretical structural analyses for the larger, more costly or critical buildings to be constructed in seismically active regions, while simply requiring that ordinary structures conform to local building codes. Economic realities usually determine the goal, not of preventing all damage in all earthquakes, but of minimizing damage in moderate, more common earthquakes and ensuring no major collapse at the strongest intensities. An essential part of what goes into engineering decisions on design and into the development and revision of earthquake-resistant design codes is therefore seismological, involving measurement of strong seismic waves, field studies of intensity and damage, and the probability of earthquake occurrence.

EXPLORATION OF THE EARTH'S INTERIOR WITH SEISMIC WAVES

Seismological methods and earthquake tomography. Seismological data on the Earth's deep structure come from several sources. These include *P* and *S* waves in earthquakes and nuclear explosions, the dispersion of surface waves from distant earthquakes, and vibrations of the whole Earth from large earthquakes.

One of the major aims of seismology is to infer the minimum set of properties of the Earth's interior that will explain recorded wave trains in detail. Notwithstanding the tremendous progress made in the exploration of the

Earth's deep structure during the first half of the 20th century, realization of this goal was severely limited until the 1960s because of the laborious effort required to evaluate theoretical models and to process the large amounts of seismological data recorded. The application of high-speed computers with their enormous storage and rapid retrieval capabilities opened the way for major advances in both theoretical work and data handling.

Since the mid-1970s researchers have studied realistic models of the Earth's structure that include continental and oceanic boundaries, mountains, and alluvial valleys rather than simple structures such as those involving variation only with depth. They also have resorted to statistical analyses that entail the simultaneous analyses of worldwide recordings of earthquake waves. In addition, various developments have benefited observational seismology. For example, the implications of seismic exploratory techniques developed by the petroleum industry (*e.g.*, seismic reflection) have been recognized and the procedures adopted. (For a discussion of these techniques, see EXPLORATION: *Exploration of the Earth's surface and interior.*) Equally significant has been the application of graphical methods to the exploration of the Earth's deep structure. This has been made possible by the development of minicomputers and microprocessors with peripheral display equipment.

Principal method for determining the Earth's deep structure

The major method for determining the structure of the Earth's deep interior is the detailed analysis of seismograms of seismic waves. (It is of interest that such earthquake readings also provide close estimates of wave velocities, density, and elastic and inelastic parameters in the Earth.) The primary procedure is to measure the travel times of various wave types, such as *P* and *S*, from their source to the recording seismograph. First, however, identification of each wave type with its ray path through the Earth must be made.

In Figure 5 seismic rays for many paths of *P* and *S* waves leaving the earthquake focus *F* are shown. Rays corresponding to waves that have suffered reflection at the Earth's outer surface (or possibly at one of the interior discontinuity surfaces) are denoted as *PP, PPP, SS, SSS, PS, SP, PPS,* etc. For example, *PS* corresponds to a wave that is of *P* type before surface reflection and of *S* type afterward. In addition, there are rays such as *pPP, sPP,* and *sPS,* the symbols *p* and *s* corresponding to an initial ascent to the outer surface as *P* or *S* waves, respectively. *PdP* is the *P* wave reflected from a discontinuity depth *d* kilometres in the upper part of the Earth.

An especially important class of rays is associated with a discontinuity surface that occurs at a depth of about 2,900 kilometres below the outer surface separating the central core of the Earth from the mantle. The symbol *c* is used to indicate an upward reflection at this discontinuity. Thus if a *P* wave travels down from a focus to the discontinuity surface in question, the upward reflection into an *S* wave is recorded at an observing station as the ray *PcS* and similarly with *PcP, ScS,* and *ScP.* The symbol *K* is used to denote the part (of *P* type) of the path of a wave that passes through the central core. Thus, the ray *SKS* corresponds to a wave that starts as an *S* wave, is refracted into the central core as a *P* wave, and is refracted back into the mantle wherein it finally emerges as an *S* wave. Such rays as *PKKP* correspond to waves that have suffered an internal reflection at the boundary of the central core.

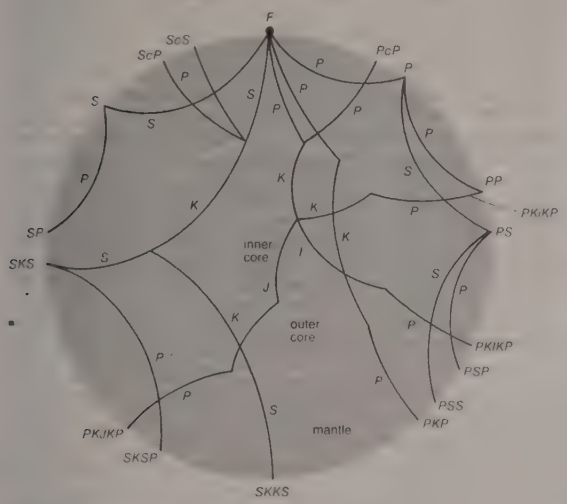

Figure 5: Seismic ray types in Earth's interior from earthquake at *F*.

The discovery of the existence of an inner core in 1936 by the Danish seismologist Inge Lehmann made it necessary to introduce additional basic symbols. For paths of waves inside the central core, the symbols *i* and *I* are used analogously to *c* and *K* for the whole Earth; therefore *i* indicates reflection upward at the boundary between the outer and inner portions of the central core, and *I* corresponds to the part (of *P* type) of the path of a wave that lies inside the inner portion. Thus, for instance, discrimination needs to be made between the rays *PKP, PKiKP,* and *PKIKP.* The first of these corresponds to a wave that has entered the outer portion of the central core but has not reached the inner portion; the second to one that has been reflected upward at the boundary between the two portions; and the third to one that has penetrated into the inner portion.

By combining the symbols *p, s, P, S, c, K, i, I,* and *d* in various ways, notation is developed for all the main rays associated with body earthquake waves. The symbol *J* has been introduced to correspond to *S* waves in the inner core, should evidence be found for such waves.

Finally, the use of times of travel along rays to infer hidden structure is analogous to the use of X rays in medical tomography. The method involves reconstructing an image of internal anomalies from measurements made at the outer surface. Nowadays, hundreds of thousands of travel times of *P* and *S* waves are available in earthquake catalogs for the tomographic imaging of the Earth's interior and the mapping of internal structure.

Structure of the Earth's interior. Studies with earthquake recordings have given a picture inside the Earth of, on average, a solid but layered mantle about 2,900 kilometres thick, which in places lies within 10 kilometres of the surface under the oceans. The thin rock layer surrounding the mantle is the crust, whose lower boundary is called the Mohorovičić Discontinuity.

In normal continental regions of 30- to 40-kilometre thickness, there is usually a superficial low-velocity sedimentary layer underlain by a zone in which seismic velocity increases with depth. This may be followed by a layer in which *P*-wave velocities in some places fall from 6 to 5.6 kilometres per second. The middle part of the crust is characterized by a heterogeneous zone with *P* velocities of nearly 6 to 6.3 kilometres per second. The lowest layer of the crust (about 10 kilometres thick) has significantly higher *P* velocities ranging up to nearly 7 kilometres per second.

In the deep ocean, under a sedimentary layer of about one-kilometre thickness, the lower layer of the thin oceanic crust is inferred to consist of basalt, which formed where extrusions of basaltic magma at mid-ocean ridges have been added to the upper part of lithospheric plates as they spread away from the ridge crests. This crustal layer cools as it moves away from the ridge crest, and its seismic velocities increase correspondingly.

Below the mantle lies a 2,255-kilometre-thick shell, which seismic waves show to have the properties of a liquid. At the very centre of the planet is a separate solid core, with a radius of 1,216 kilometres. Recent work with observed seismic waves has revealed fine structural details within the main shells inside the Earth, especially the crust and lithosphere. These regional variations are important in explaining the dynamic history of the planet.

Long-period oscillations of the globe. Sometimes earthquakes are large enough to cause the whole Earth to ring like a bell. The deepest tone of vibration of the planet is one of 54 minutes. Knowledge of these vibrations has come from a remarkable extension in the range of periods of ground movements that can be recorded by very long-period seismographs, thus allowing the interval in earthquake wave periods to be filled in: from ordinary *P* waves

with periods of a few seconds to vibrations with periods on the order of 12 and 24 hours such as those that occur in Earth tidal movements.

The measurements of the vibrations of the whole Earth provide important additional data on the properties of the interior of the planet. It should be emphasized that these free vibrations are set up by the energy release of the earthquake source but continue for many hours and sometimes even days. For an elastic sphere like the Earth two types of vibrations are known to be possible. In one type, called *S* modes or spheroidal vibrations, the motions of the elements of the sphere have components along the radius as well as along the tangent. In the second type, which are designated as *T* modes or torsional vibrations, there are shear but no radial displacements. The nomenclature is ${}_nS_\ell$ and ${}_nT_\ell$, where the letters n and ℓ are related to the surfaces in the vibration at which there is zero motion. Four examples are illustrated in Figure 6. The suffix n gives a count of the number of internal zero-motion (nodal) surfaces and the suffix ℓ indicates the number of surface nodal lines.

Spheroidal and torsional vibrations

Several hundred types of *S* and *T* vibrations have been identified and the associated periods measured. In a smaller number of cases, the amplitude of the ground motion in the vibrations has been determined for particular earthquakes, and, more importantly, the attenuation of each component vibration has been measured. The measure of this decay constant is called the quality factor *Q*. The greater the value of *Q*, the less is the wave or vibration damping. Typically, for ${}_0S_{10}$ and ${}_0T_{10}$, the *Q* values are about 250.

The rate of decay of the vibrations of the whole Earth with the passage of time can be seen in Figure 7, where they appear superimposed for 20 hours of the 12-hour tidal deformations of the Earth. At the bottom of Figure 7, these vibrations have been split up into a series of peaks, each with a definite frequency, like the spectrum of light. Such a spectrum indicates the relative amplitude of each harmonic present in the free oscillations. If the physical properties of the Earth's interior were known, all these individual peaks could be calculated directly. Instead, the internal structure must be estimated from the observed peaks.

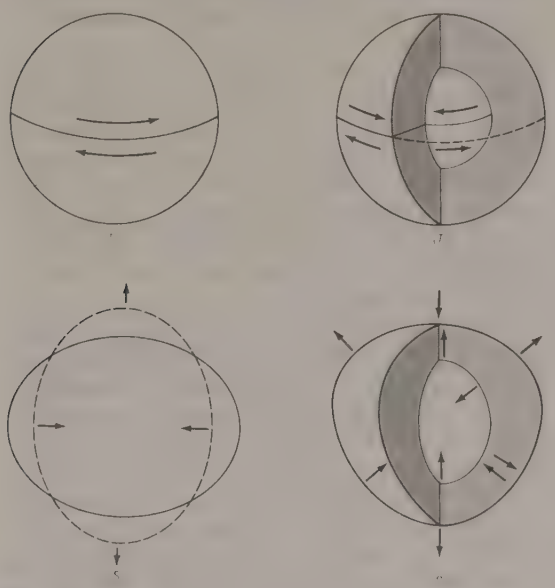

Figure 6: Displacements in the Earth in four types of free vibrations.

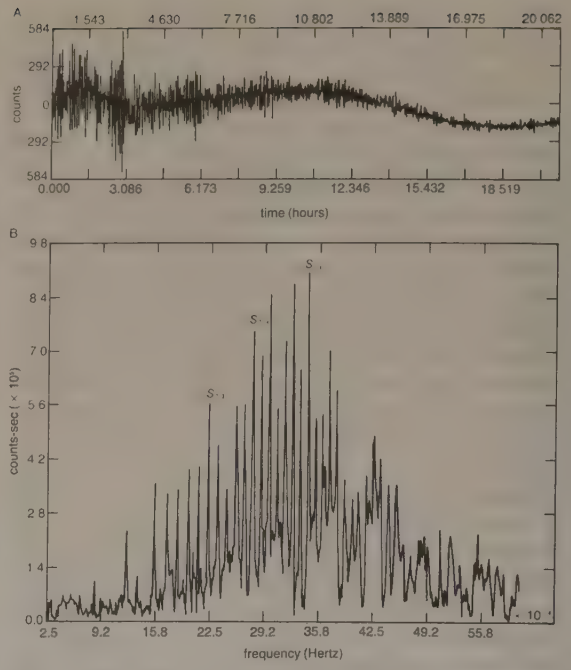

Figure 7: (A) Recorded ground motion for 20 hours at Whiskeytown, Calif., in the large Indonesian earthquake, 1977. (B) Frequency spectrum of the Earth's oscillations from the record in A above.

Recent research has shown that observations of long-period oscillations of the Earth discriminate fairly finely between different Earth models. In applying the observations to improve the resolution and precision of such representations of the planet's internal structure, a considerable number of Earth models are set up and all the periods of their free oscillations are computed and checked against the observations. Models can then be steadily eliminated until only a small range remains. In practice, the work starts with existing models; efforts are made to amend them by successive steps until full compatibility with the observations is achieved within the uncertainties of the observations. Even so, the resulting computed Earth structure is not a unique solution to the problem.

BIBLIOGRAPHY. The subject of earthquakes is dealt with mainly in books on seismology. Recommended elementary texts are BRUCE A. BOLT, *Earthquakes: A Primer* (1978), and *Inside the Earth: Evidence from Earthquakes* (1982); and CHARLES F. RICHTER, *Elementary Seismology* (1958). Interesting discussions are also given by G.A. EIBY, *Earthquakes* (1967, reissued 1980); and KARL V. STEINBRUGGE, *Earthquakes, Volcanoes, and Tsunamis: An Anatomy of Hazards* (1982). More advanced texts that treat the theory of seismic waves in detail are K.E. BULLEN and BRUCE A. BOLT, *An Introduction to the Theory of Seismology*, 4th ed. (1985); and KEIITI AKI and PAUL J. RICHARDS, *Quantitative Seismology: Theory and Methods*, 2 vol. (1980). On the seismicity of the Earth, the most comprehensive treatment is still B. GUTENBERG and CHARLES F. RICHTER, *Seismicity of the Earth and Associated Phenomena*, 2nd ed. (1954, reprinted 1965); see also J.P. ROTHÉ, *The Seismicity of the Earth, 1953–1965* (1969). For a broad view of prediction, there is TSUNEJI RIKITAKE, *Earthquake Prediction* (1976). On a history of discrimination between underground nuclear explosions and natural earthquakes, see BRUCE A. BOLT, *Nuclear Explosions and Earthquakes: The Parted Veil* (1976).

East Asian Arts

The term East Asia, as used in this article, comprises China, Korea, and Japan. Some studies of East Asia also include the cultures of the Indochinese peninsula and adjoining islands, as well as Mongolia to the north. The logic of this occasional inclusion is based on a strict geographic definition as well as a recognition of common bonds forged through the acceptance of Buddhism by many of these cultures. China, Korea, and Japan, however, have been uniquely linked for several millennia by a common written language and by broad cultural and political connections that have ranged in spirit from the uncritically adorational to the contentious.

From ancient times, China has been the dominant and referential culture in East Asia. Although variously developed Neolithic cultures existed on the Korean Peninsula and on the Japanese archipelago, archaeological evidence in the form of worked stone and blades from the Paleolithic and Neolithic periods suggests an exchange between the early East Asian cultures and the early introduction of Chinese influence. This cultural interaction was facilitated in part by land bridges that connected Japan with the continent.

Significant developments in the production of earthenware vessels from about 10,000 BC in Japan (thus far, the world's earliest dated pottery) and from approximately 3500 BC in Korea are well documented. They reveal a rich symbolic vocabulary and decorative sense as well as a highly successful union of function and dynamic form. These types of vessels chronicle the increasing needs for storage as there was a gradual societal transformation from nomadic and foraging cultures to more sedentary crop-producing cultures. There were pottery-dominant cultures in China as well. The painted (*c.* 5000 BC) and black (*c.* 2500 BC) earthenware are the best known.

As Korea and Japan continued in various Neolithic phases, developments in China from approximately 2000 BC were far more complex and dramatic. Archaeological evidence firmly corroborates the existence of an emerging bronze culture by approximately 2000 BC. This culture provided the base for Shang dynasty (approximately from the 16th to the 11th century BC) culture, which witnessed extraordinary developments in the production of bronze, stone, ceramic, and jade artifacts as well as the development of a pictograph-based written language. Bronze production and the expansion of rice cultivation gradually appeared in Korea from approximately 700 BC and then slightly later in Japan. While no single political event seemed to further the transmission of Chinese cultural elements to Korea and Japan, clearly the expansionist policies of the rulers of the Han dynasty (206 BC–AD 220) stimulated what had been a gradual assimilation of Chinese cultural elements by both Korea and Japan. Indicatively, it is from this period that Chinese documentation of legation visits to Japan provide the first written records describing the structure of Japanese society.

The cultures of China, Korea, and Japan went on, from this period of interaction during the Han dynasty, to develop in quite distinctive ways. China, for example, experienced two major dynasties, the Han and the T'ang (618–907), that were truly international in scope and easily rivaled contemporary Mediterranean powers. In succeeding dynasties, including rule by foreign invaders from the north, the development of the visual arts continued to explore and develop the basic media for which the Chinese demonstrated special affinity: clay, jade, lacquer, bronze, stone, and the various manifestations of the brush, especially in calligraphy and painting. Emphases shifted, as did styles, but the fundamental symbolic vocabulary and a predisposition to renew through reinterpretation and reverence of the past was characteristic not only of Chinese but of all the East Asian arts.

Korea's pivotal location gave it particular strategic value and thus made it the target of subjugation by a stronger China and Japan. But Korea strove to maintain its own identity and to prevent China and Japan from exercising control over more than a small portion of the peninsula. National contributions to the larger aesthetic culture of East Asia included unequaled mastery of goldsmithing and design as well as a ceramic tradition that included delicate celadon ware and a vigorous folk ware that inspired generations of Japanese tea masters. Indeed, Korea was a primary conduit of continental culture to the Japanese in many areas of visual expression, including metalwork, painting, and ceramics.

In the late 13th century, Mongol forces made two unsuccessful attempts at invading the Japanese islands, and the country was spared occupation by a foreign power until well into the 20th century. This unusual condition of comparative isolation provided Japanese cultural arbiters with a relative freedom to select or reject outside styles and trends. Nevertheless, Chinese art's highly developed, systematic forms of expression, coupled with its theoretical basis in religion and philosophy, proved enormously forceful, and Chinese styles dominated at key junctures in Japanese history. The reception and assimilation of outside influence followed by a vigorous assertion of national styles thus characterized the cycle of Japanese cultural development. In addition to distinctive reinterpretations of Chinese ink monochrome painting and calligraphy, an indigenous taste for the observation and depiction of human activity and an exquisitely nuanced sense of design are readily apparent in most areas of Japanese visual expression, none more so than in narrative painting and in the woodblock print.

The elements and tendencies common to the Chinese, Korean, and Japanese cultures are vast, but two kinds of visual expression are especially important: a strong affinity for the clay-formed vessel and calligraphic expression through the ink-charged brush. Vigorous, subtle, and technically sophisticated expressions ranging from Neolithic earthenware to celadon and glazed enamelware were both integral to daily life and prized by connoisseurs who judged ceramics by an elaborate code of appreciation. Increasingly abstracted forms of pictographs provided a means of writing that was image-based; characters formed by the brush could be normative but also offered infinite possibilities for personal expression through ink modulation and idiosyncratic gesture. Although Korea and Japan later developed phonetic syllabaries, the visual language of the educated continued to be based on the ancestral Chinese form. The meanings of words, phrases, or whole texts could be expanded or nuanced by their visual renderings. Painting was derivative from calligraphy, and implicit in painting skill was a preceding mastery of the brush-rendered calligraphic line. As a consequence, calligraphy was unequaled as the major element in the transmission of cultural values, whether as information or as aesthetic expression.

The influence of Buddhism, a force which was initially foreign to East Asia, also should not be underestimated. Emerging from India and Central Asia in the first century after nearly 500 years of development on the subcontinent, Buddhism offered a convincing universalist system of belief that assimilated and frequently gave visual expression to indigenous religions. By the 5th century AD, a Chinese dynastic line had adopted Buddhism as a religion of state. While individual rulers, courts, or dynasties at times propelled the florescence of East Asian arts, none of them equaled the patronage of Buddhism in duration, scale, and intellectual sustenance. Confucianism, Taoism, and, to a somewhat lesser degree, Shintō required expression through the arts; however, Buddhism's multiple

sects, complex iconography, and program of proselytizing made it the natural and dominant vehicle of transcultural influence in East Asia.

The unity and diversity of the three East Asian cultures are explored in greater depth in the article, which treats both the visual and the performing arts. The literatures of the respective languages are treated individually in the *Macropædia*. (J.T.U.)

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, sections 613, 622, 624, 625, 626, 627, and 629, and the *Index*.

The article is divided into the following sections:

VISUAL ARTS

Chinese visual arts

The present political boundaries of China, which include Tibet, Inner Mongolia, Sinkiang, and the northeastern provinces formerly called Manchuria, embrace a far larger area of East Asia than will be discussed here. "China Proper," as it has been called, consists of 18 historical provinces bounded by the Tibetan Highlands on the west, the Gobi to the north, and Myanmar (Burma), Laos, and Vietnam to the southwest; and it is primarily the arts of this area that will be treated here.

The first communities that can be identified culturally as Chinese were settled chiefly in the basin of the Huang Ho (Yellow River). Gradually they spread out, influencing other tribal cultures, until, by the Han dynasty (206 BC–AD 220), most of China proper was dominated by the culture that had been formed in the "cradle" of northern Chinese civilization. Over this area there slowly spread a common written language, as well as a common belief in the power of heaven and the ancestral spirits to influence the living and in the importance of ceremony and sacrifice to achieve harmony among heaven, nature, and humankind. These beliefs were to have a great influence on the character of Chinese art.

Chronology of Chinese art

The Chinese themselves were among the most historically conscious of all the major civilizations and were intensely aware of the strength and continuity of their cultural tradition. They viewed history as a cycle of decline and renewal associated with the succession of ruling dynasties. Both the political fragmentation and social and economic chaos of decline and the vigour of dynastic rejuvenation could stimulate and colour important artistic developments. Thus, it is quite legitimate to think of the history of Chinese art, as the Chinese themselves do, primarily in terms of the styles of successive dynasties.

GENERAL CHARACTERISTICS

Aesthetic characteristics and artistic traditions. *Art as a reflection of Chinese class structure.* One of the outstanding characteristics of Chinese art is the extent to which it reflects the class structure that has existed at different times in Chinese history. Up to the Warring States period (475–221 BC), the arts were produced by anonymous craftsmen for the royal and feudal courts. During the Warring States and the Han dynasty, the growth of a landowning and merchant class brought new patrons; and after the Han there began to emerge the concept of "fine art" as the product of the leisure of the educated gentry, many of whom were amateur practitioners of the arts of poetry, music, calligraphy, and, eventually, painting. At this time a distinction began to arise between the lower-class professional and the elite amateur artist that was to have a great influence on the character of Chinese art in later times. Gradually one tradition became increasingly identified with the artists and craftsmen who worked for the court or sold their work for profit. Identified with another tradition, the scholarly amateurs looked upon such people with some contempt, and the art of the literati became increasingly refined and rarefied to the point that, from the Sung dynasty (960–1279) onward, an assumed awkwardness in technique was admired as a mark of the amateur and gentleman. One effect of the revolutions of the 20th century has been the breaking down of the class barriers between amateur and professional and even, during the Great Proletarian Cultural Revolution of 1966–76, an emphasis on anonymous, proletarian-made art like that of the T'ang dynasty (618–907) and earlier.

The role of calligraphy in Chinese art. Since the 3rd century AD, calligraphy, or writing as a fine art, has been considered supreme among the visual arts in China. Not only does it require immense skill and fine judgment, but it is regarded as uniquely revealing of the character and breadth of cultivation of the writer. Since the time when inscribed oracle bones and tortoise shells (China's oldest extant writing) were used for divination in the Shang dynasty (16th to 11th centuries BC), calligraphy has been associated with spiritual communication and has been viewed in terms of the writer's own spiritual attunement. To fully appreciate calligraphy, as to produce it, requires lofty personal qualities and unusual aesthetic sensitivity.

The Chinese painter uses essentially the same materials as the calligrapher—brush, ink, and silk or paper—and the Chinese judge his work by the same criteria, basically the vitality and expressiveness of the brushstroke itself and the harmonious rhythm of the whole composition. Painting in China, therefore, is essentially a linear art. The painters of most periods were concerned less with striving for originality or conveying a sense of reality and three-dimensional mass through such aids as shading and perspective, concentrating instead on transmitting to silk or paper, through the rhythmic movement of the brushstroke, an awareness of the inner life of things.

The aesthetics of line in calligraphy and painting have had a significant influence on the other arts in China.

Influence of painting and calligraphy on the other arts

In the motifs that adorn the ritual bronzes, in the flow of the drapery over the surface of Buddhist sculpture, in the decoration of lacquerware, pottery, and cloisonné enamel (wares decorated with enamel of different colours separated by strips of metal), it is the rhythmic movement of the line, following the natural movement of the artist's or craftsman's hand, that to a large extent determines the form and gives to Chinese art as a whole its remarkable harmony and unity of style. (For information about Chinese calligraphy, see the article WRITING: *East Asian calligraphy*.)

Characteristic themes and symbols. In early times this sense of attunement involved submission to the Will of Heaven through ritual and sacrifice, and it was the function of Chinese art to serve these ends. Archaic bronze vessels were made for sacrifices to heaven and to the spirits of clan ancestors, who were believed to influence the living for good if the rites were properly and regularly performed. Chinese society, basically agricultural, has always laid great stress on the need for humans to understand the pattern of nature and to live in accordance with it. The world of nature was seen as the visible manifestation of the workings of the Great Ultimate through the generative interaction of the yin-yang (female-male) dualism. As it developed, the purpose of Chinese art turned from propitiation and sacrifice to the expression of human understanding of these forces through the painting of landscape, bamboo, birds, and flowers. This might be called the metaphysical, Taoist aspect of Chinese painting.

Particularly in early times, art also had social and moral functions. The earliest paintings referred to in ancient texts depicted on the walls of palaces and ancestral halls benevolent emperors, sages, virtuous ministers, loyal generals, and their evil opposites as examples and warnings to the living. Portrait painting also had this moral function, depicting not the features of the subject so much as his character and his role in society. Court painters were called upon to depict auspicious and memorable events. This was the ethical, Confucian function of painting.

High religious art as such is foreign to China. Popular folk religion was seldom an inspiration to great works of art, and Buddhism, which indeed produced many masterpieces of a special kind, was a foreign importation.

Themes not represented in Chinese art

Among the typical themes of Chinese art there is no place for war, violence, the nude, death, or martyrdom. Nor is inanimate matter ever painted for art's sake: the very rocks and streams are felt to be alive, visible manifestations of the invisible forces of the universe. No theme would be accepted in Chinese art that was not inspiring, noble, refreshing to the spirit, or at least charming. Nor is there any place in the Chinese artistic tradition for an art of pure form divorced from content, and the Chinese cannot conceive of a work of art of which the form is beautiful while the subject matter is unedifying. In the broadest sense, therefore, all Chinese art is symbolic, for everything that is painted reflects some aspect of a totality of which the painter is intuitively aware. At the same time Chinese art is full of symbols of a more specific kind, some with various possible meanings.

General media characteristics. *Architecture.* Because the Chinese build chiefly in timber, which is vulnerable to fire and the ravages of time, very little ancient architecture has survived. The oldest datable timber building is the small main hall of the Nan-ch'an Temple, on Mount Wu-t'ai in Shansi province, built sometime before 782 and restored in that year. Brick and stone are used for defensive walls, the arch for gates and bridges, and the vault for tombs. Only rarely has the corbeled dome (in which each successive course projects inward from the course below it) been used for temples and tombs. Single-story architecture predominates throughout northern and much of eastern China, although multistory building techniques date to the late Chou dynasty (11th century–255 BC).

The basic elements in a Chinese timber building are the platform of pounded earth faced with stone or tile on which the building stands; the post-and-lintel frame (vertical posts topped by horizontal tie beams); the roof-supporting brackets and truss; and the tiled roof itself. The walls between the posts, or columns, are not load-bearing, and the intercolumnar bays (odd-numbered along the front of the building) may be filled by doors (usually doubled) or by brick or such material as bamboo wattle faced with plaster, or they may be left open to create peristyles. The flexible triangular truss is placed transverse to the front side of the building and defines a gable-type roof by means of a stepped-up series of elevated tie beams (*t'ai-liang*, for which this entire system of architecture is named); the beams are sequentially shortened and alternate with vertical struts that bear the roof purlins and the main roof beam. The flexible proportions of the gable-end framework of struts and beams permits the roof to take any profile desired, typically a low and rather straight silhouette in northern China before the Sung, and increasingly elevated and concave in the Sung, Yüan, Ming, and Ch'ing. The gable-end framework is typically moved inward in a prominent building and partially masked in a hip-and-gable (or half-hip) roof and completely masked in a full-hipped roof. The timber building is limited in depth by the span of the truss; in theory, however, it may be of any length, although it rarely exceeds 11 bays in practice.

The origin of the distinctive curve of the roof, which first appeared in China about the 6th century AD, is not fully understood, although a number of theories have been put forward.

The "pavilion concept"

In the "pavilion concept," whereby each building is conceived of as a freestanding rectilinear unit, flexibility in the overall design is achieved by increasing the number of such units, which are arranged together with open, connecting galleries around courtyards; diversity is achieved through design variations that individualize these courtyard complexes. In the private house or mansion, the grouping of halls and courtyards is informal, apart from the axial arrangement of the entrance court with its main hall facing the gateway; but in a palace such as the gigantic Forbidden City in Peking, the principal halls are ranged with their courtyards behind one another on a south-to-north axis, building up to a ceremonial climax and dying away to lesser courts and buildings to the north. Ancestral halls and temples follow the palatial arrangement. The scale of a building, the number of bays, the unit of measure used for the timbers, whether bracketing is included or not, and the type of roof (gabled, half- or full-hipped, with or without prominent decorative ridge-tiling and prominent overhang) all accord with the placement and significance of the building within a courtyard arrangement, with the relative importance of that courtyard within a larger compound, and with the absolute status of the whole building complex. The entire system, therefore, is modular and highly standardized.

The domination of the roof allows little variation in the form of the individual building; thus, aesthetic subtlety is concentrated in pleasing proportions and in details such as the roof brackets or the plinths supporting the columns. T'ang architecture achieved a "classic" standard, with massive proportions yet simple designs in which function and form were fully harmonized. Architects in the Sung dynasty were much more adventurous in playing with interlocking roofs and different levels than were their successors in later centuries. The beauty of the architecture of the Ming dynasty (1368–1644) and Ch'ing dynasty (1644–1911/12) lies rather in the lightweight effect and the richness of painted decoration.

Painting and calligraphy. The character of Chinese painting and calligraphy is closely bound up with the nature of the medium. The basic material is ink, formed into a short stick of hardened pine soot and glue, which is rubbed to the required consistency on an inkstone with a little water. The calligrapher or painter uses a pointed-tipped brush made of the hair of goat, deer, or wolf set in a shaft of bamboo. He writes or paints on a length of silk or a sheet of paper, the surface of which is absorbent, allowing no erasure or correction. He must therefore know beforehand what he intends to do, and the execution demands confidence, speed, and a mastery of technique acquired only by long practice. For example, to broaden the brush stroke, the calligrapher or painter applies downward pressure on the brush. Such subtle action of the highly flexible but carefully controlled brush tip determines the

dynamic character of the brushwork and is the primary focus of attention of both the artist and critical viewers.

In painting, colour is added, if at all, to make the effect more true to life or to add decorative accent and rarely as a structural element in the design, as in Western art. Brighter, more opaque pigments derived from mineral sources (blue from azurite, green from malachite, red from cinnabar or lead, yellow from orpiment or ochre, all produced in various intensities) are preferred for painting on silk, while translucent vegetable pigments predominate in painting on paper (indigo blue, red from safflower or madder, vegetable green, rattan and sophora plant yellow) and produce a lighter, more delicate effect.

While painting on dry plaster walls or screens is an ancient art in China, more common formats in the past millennium have been the vertical hanging scroll, perhaps derived from the Buddhist devotional banner, and the horizontal hand scroll, which may be of any length up to about 15 metres (50 feet). Other forms are fan painting and the album leaf. The artist's carefully placed signature, inscription, and seals are an integral part of the composition. In Chinese eyes a picture may gain considerably in interest and value from the colophons added by later connoisseurs on the painting itself or, in the case of a hand scroll, mounted after it. The mounting of paintings and calligraphy is a highly skilled craft and, if carefully done, will enhance the appearance of a scroll and ensure its preservation for many centuries.

Sculpture. With rare exceptions, sculptors were regarded as mere craftsmen, and very few of their names are known. Works of sculpture were created not (like paintings) as art objects in themselves but for a specific ceremonial, religious, or funerary purpose. While small figures were carved in stone in the Shang dynasty, large-scale stone sculpture is a later development, possibly stimulated by contacts with western Asia in the Han dynasty. Major works of religious sculpture did not appear until Buddhism had taken firm root in northern China after the Han dynasty.

Clay modeling and bronze casting

More truly Chinese than stone carving is the tradition of clay modeling and its derivative, bronze casting. Tomb figurines of remarkable plasticity and liveliness were made from the Ch'in dynasty (221–206 BC) through the T'ang dynasty, while some temple sculpture was carried out on a large scale in clay, using straw or cotton as a binder. The aesthetic of the fluid medium of clay modeling, which follows the natural movement of the craftsman's hand and arm, is influenced by that of painting and calligraphy, which even affected the more intractable media of stone and wood carving.

In Sung and later times, the distinctive, abstract medium of assembling stones as "false mountains" (*chia-shan*) in royal parks and scholars' gardens came to the forefront of the Chinese sculptural arts.

Jade, lacquer, textiles, and other media. Other major art forms of China include pottery, jade carving, metalwork (including gold and silver inlay and cloisonné enamel), textiles, and lacquerware. In several of these, China can claim a long priority over the rest of the world. True pottery glazes were developed in China before the end of the 2nd millennium BC and porcelain by the 6th century, more than 1,000 years before its discovery in Europe; jade carving, sericulture (the raising of silkworms), and weaving of silk go back to Neolithic times and lacquer painting to the Shang dynasty. Bronze casting, while not so ancient as that of the Middle East, reached by 1000 BC a perfection of beauty and craftsmanship not matched in the ancient Western world. In point of style, all these arts share with sculpture a debt to pictorial art and an aesthetic based on the rhythmic movement of the line.

Jade

Jade occupies a special place in Chinese artistic culture, valued as gold is in the West but hallowed with even loftier moral connotations. Because of this and the belief in its indestructibility, jade from early times was lavishly used not only for dress ornaments but also for ritual objects, both Confucian and Taoist, and for the protection of the dead in the tomb.

The jade stone used since ancient times in China is nephrite, a crystalline calcium magnesium silicate, which in its pure state is white but may be green, cream, yellow, brown, gray, black, or mottled owing to the presence of impurities, chiefly iron compounds. Generically, the Chinese used the term *yü* to cover a variety of related "jade" stones, including nephrite, bowenite, and jadeite. In the Neolithic Period, by the mid-4th millennium BC, jade from Lake T'ai (in Kiangsu province) began to be used by southeastern culture groups, while deposits along the Liao River in the northeast (called "Hsiu-yen jade," probably bowenite) were utilized by the Hung-shan culture. In historic times, China's chief source of nephrite has been the riverbeds of Yarkand and Ho-t'ien in present-day Sinkiang autonomous region in northwestern China, where jade is found in the form of boulders. Since the 18th century, China has received from northern Myanmar (upper Burma) a brilliant green jadeite (also called *feitsui,* or "kingfisher-feathers") that is a granular sodium-aluminum silicate harder than but not quite so tough as nephrite. Having a hardness like that of steel or feldspar, jade cannot be carved or cut with metal tools but has to be laboriously drilled, ground, or sawed with an abrasive paste and rotational or repetitive-motion machinery, usually after being reduced to the form of blocks or thin slabs.

The Chinese had discovered as early as the Shang dynasty that the juice of the lac tree, a naturally occurring polymer, could be used for forming hard but lightweight vessels when built up in very thin layers through the repeated dipping of a core of carved wood, bamboo, or cloth. With the addition of pigments, most commonly red and black, less frequently green and yellow, it could also be used for painting and decorating the outer layers of these vessels. Being sticky, painted lacquer must be applied slowly with the brush, giving rise to prolonged motions and fluid, often elegantly curvilinear designs. Since lacquer is almost totally impervious to water, vessels and wine cups have been excavated in perfect condition from waterlogged graves of the late-5th-century-BC Tseng state in Sui-hsien, of the 4th–3rd-century-BC Ch'u state in Chiang-ling (now Sha-shih), and of the early-2nd-century-BC Han dynasty in Ch'ang-sha. Such works ranged from large-scale coffins to bird- or animal-shaped drum stands to such daily utensils as nested toiletry boxes and food-serving implements. By the Warring States period, lacquerwork had developed into a major industry; and, being approximately 10 times more costly than their bronze equivalents, lacquer vessels came to rival bronzes as the most esteemed medium for providing offerings in ancestral ceremonies among the wealthy aristocracy.

Sericulture

It was the Chinese who first discovered that the roughly 1 kilometre (1,000 yards) of thread that constitutes the cocoon of the silkworm, *Bombyx mori,* could be reeled off, spun, and woven; and sericulture early became an important feature of Chinese rural economy. Its place in Chinese culture is indicated by the legend that it was the wife of the mythical Yellow Emperor, Huang-ti, who taught the Chinese people the art and by the fact that in historic times the empress was ceremonially associated with it. The weaving of damask probably existed in the Shang dynasty, and the 4th–3rd-century-BC tombs at Ma-shan near Chiang-ling (Hupeh province, excavated in 1982) have provided outstanding examples of brocade, gauze, and embroidery with pictorial designs as well as the first complete garments. Although transportation westward across Central Asia's trade route brought Chinese silks to many parts of the Mediterranean region, the knowledge of silk production techniques did not reach the area until the 6th century AD.

STYLISTIC AND HISTORICAL DEVELOPMENT

Formative period. The earliest evidence for art in any form in ancient China consists of crude cord-marked pottery and artifacts decorated with geometric designs found in Mesolithic sites in northern China and in the Kwangtung-Kwangsi regions. The dating for prehistoric culture in China is still very uncertain, but this material is probably at least 7,000 or 8,000 years old. The art of the Neolithic Period represents a considerable advance. The Yang-shao, or Painted Pottery, culture (named after the first Neolithic site discovered, in 1920), which had its centre around the

eastern bend of the Huang Ho, is now known to have extended across northern China and up into Kansu province. Yang-shao pottery consists chiefly of full-bodied funerary storage jars made by the coiling, or ring, method. They are decorated, generally on the upper half only, with a rich variety of geometric designs, whorls, volutes, and sawtooth patterns executed in black and red pigment with a brush whose sweeping, rhythmic lines foreshadow the free brush painting of historic periods. Some of the pottery from the village site of Pan-p'o (*c.* 4500 BC), discovered in 1953 near Sian in Shensi, bear schematized fish, bird, deer, and plant designs, which are related thematically to hunting and gathering, and what may be a human face or mask. Dating for the dominant phase of Yang-shao culture may be put roughly between 5000 and 3000 BC. Over this span of two millennia the Yang-shao culture progressed generally westward along the Huang Ho and Wei River valleys from sites in central China, Kansu province, such as Pan-p'o, to sites including Miao-ti-kou, Ma-chia-yao, Pan-shan, and Ma-ch'ang. The art produced at these villages exhibits a clear and logical stylistic evolution, leading from representational designs to linear abstraction (the latter with occasional symbolic references).

Lung-shan culture

The last major phase of the Neolithic Period is represented by Lung-shan culture, distinguished particularly by the black pottery of its later stages (*c.* 2200–1700 BC). Lung-shan is named after the site of its discovery in 1928, in Shantung province, although evidence increasingly suggests origins to the south along the China coast, in Kiangsu province. By contrast with the Yang-shao, the fully developed Lung-shan pottery is wheel-made and especially thinly potted. The finest specimens have a dark gray or black body burnished to a hard, smooth surface that is occasionally incised but never painted, giving it a metallic appearance. The occasional use of open-worked design and the simulation of lugs and folded plating all suggest the highly skilled imitation, in an inexhaustible medium, of valuable copper wares which, although no longer extant, heralded the transition from a lithic to a metallic culture. At this point, the superior calibre of Chinese ceramics was first attained.

In Yang-shao pottery, emphasis was on funerary wares. The delicate potting of the Lung-shan ware and the prevalence of offering stands and goblets suggest that these vessels were made not for burial but for sacrificial rites connected with the worship of ancestral spirits. Ritual vessels, oracle bones (used by shamans in divination), ceremonial jade objects and ornaments, and architecture (pounded-earth foundations, protective city walls, rectilinear organization) reflect an advanced material culture on the threshold of the Bronze Age. This culture continued in outlying areas long after the coming of bronze technology to the central Honan–Shensi–southern Shansi region.

The earliest examples of jade from the lower Yangtze River region appear in the latter phases of Ma-chia-pang culture (*c.* 5100–3900 BC) and continue into the 4th–3rd millennia BC in the Sung-tse and Ch'ing-lien-kang cultures of that region. Remarkably sophisticated jade pieces appear after 2500 BC in the Liang-chu culture of southern Kiangsu and northern Chekiang provinces (*c.* 3400–2200 BC), many with an apparent lack of wear and practical usage that suggests a primarily ceremonial function. These include the first examples of the flat, perforated *pi* disk, which became the symbol of heaven in later times, and of the *ts'ung*, a tube with a square exterior and cylindrical hollow centre. These two items remained part of the Chinese Imperial paraphernalia until the early 20th century. The precise meaning of the *ts'ung* and its possible association with astronomical sighting or geomantic site selection or its conjunction of yin (square, earth, female) and yang (circular, heaven, male) features remains unclear. Also present at this time, in the Liang-chu and the Shantung province Lung-shan cultures, are ceremonial *kuei* and *chang* blades and axes, as well as an increasing variety of ornamental arc-shaped and circular jade pendants, necklaces, and bracelets (often in animal form), together with the significant appearance of mask decoration, all of which link these Neolithic jades to those of the subsequent Shang period.

The *pi* and the *ts'ung*

Black pottery stem cup, Neolithic Lung-shan phase, from Jih-chao, Shantung province, *c.* late 3rd millennium BC. In the Shantung Provincial Museum, Chi-nan. Height 26.5 cm.

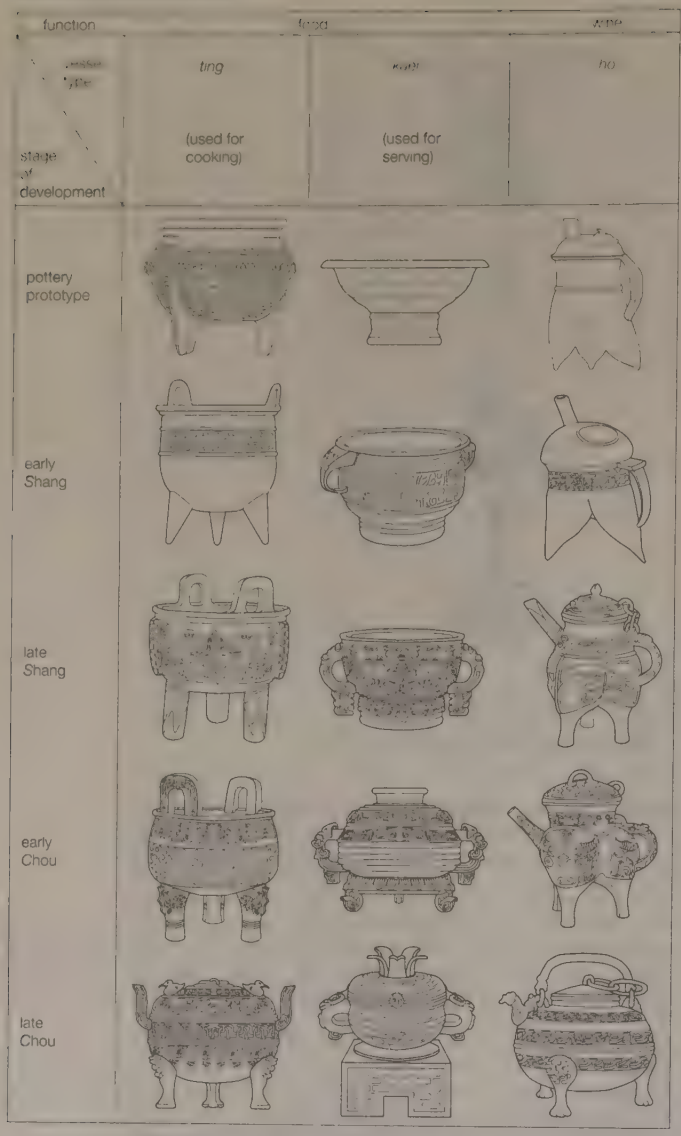
Shang dynasty (16th to 11th centuries BC). Although Chinese legends speak of the Hsia dynasty, the Shang is the first whose existence is attested by archaeological and contemporary written records. Its origins are obscure. The Shang capital was reportedly moved on a number of occasions. Erh-li-t'ou, discovered near the modern city of Lo-yang in Honan province, may represent the earliest named Shang capital, Po, if not a still earlier Hsia dynasty site. A "palace" with pounded-earth foundation, fine jades, simple bronze vessels, and oracle bones have all been found there, but the question of whether this represents the Shang dynasty or its predecessor remains uncertain for lack of any written materials. At Erh-li-kang, in the Cheng-chou area in Honan province, traces have been found of a walled city that may have been the middle Shang capital referred to as Ao. Yin, the most enduring of Shang capital sites, lasting through the reigns of the last 9 (or 12) Shang kings, was located near the modern city of An-yang, in Honan province. Its discovery in 1899 by paleographers following the tracks of tomb robbers opened the way to verification of traditional accounts of the Shang dynasty and for the first scientific examination of China's early civilization. Here, recorded on oracle bones, the written documentation for the first time is rich, archival, and wide-ranging regarding activities of the theocratic Shang government. Excavations conducted near An-yang between 1928 and 1937 provided the initial training ground for modern Chinese archaeology and continued periodically after 1949. No fewer than 14 royal tombs have been unearthed near An-yang, culminating in the 1976 excavation of the first major tomb to have survived intact—that of Fu Hao, who is believed to have been a consort of the Shang king Wu-ting and a noted military leader. The Fu Hao tomb contained more than 440 bronze vessels and 590 jade objects among its numerous exquisite works.

The Fu Hao tomb

Architecture. Excavations at Lo-yang, Cheng-chou, and An-yang have revealed rammed-earth (layers of pounded earth) foundations and postholes of timber buildings with wattle and daub walls (woven rods and twigs covered and plastered with clay) and thatched roof. The largest building yet traced at An-yang is a timber hall about 30 metres (90 feet) long, the wooden pillars of which were set on stone socles, or bases, on a raised platform. Ordinary dwellings were partly sunk beneath ground level, as in Neolithic times, with deeper storage pits inside them.



Development of bronze vessel types.

There is no sign of the structural use of brick or stone or of tile roofs in any of the An-yang sites. Royal tombs along the banks of the Huan River to the northwest of modern An-yang consisted of huge, square, rammed-earth pits approached by two or four sloping ramps. Lined and roofed with timber, the tombs were sunk in the floor of the pit. Tomb walls and coloured impressions left on the earth by carved and painted timbers include zoomorphic motifs very similar to those on ritual bronze vessels (see below). Traces of a painted clay wall found elsewhere at An-yang, in a royal stone- and jade-carving workshop, demonstrate that buildings above ground were decorated with similar designs and indicate a uniformity of design principles and themes in all media at that time.

Sculpture. While no monumental sculpture has been found at Shang sites, Shang craftsmen carved, generally out of white marble, small, seated human figures, birds, tigers, elephants, bears, and composite creatures. Most of these pieces were made as isolated objects for display or ritual purposes, but a few are socketed, showing that they once adorned a structure. These marble sculptures are compactly modeled and decorated with volutes and squared spirals similar to those on ritual bronzes. In addition to stone carvings, a small number of pottery figurines of prisoners of war have been unearthed at An-yang, the earliest instance of the custom of putting figurines of guardians and slaves in the tomb to accompany the dead.

Pottery tomb figurines

Ritual bronzes. More than any other factor, it was the unearthing at An-yang of magnificent bronze vessels that demonstrated the power and wealth of the Shang rulers. The vessels were used in divinatory ceremonies for sacrificial offerings of meat, wine, and grain, primarily to the spirits of clan ancestors, especially those of the ruler and his family. They were probably kept in the ancestral hall of the clan, and, in some cases, they were buried with their owner.

Surprisingly, perhaps, the bronze vessels were not discussed in Shang oracle bone inscriptions. But they themselves sometimes came to bear, by late Shang times, short, cast dedicatory inscriptions, providing the name of the vessel type, of the patron, and of the ancestor to whom the vessel was dedicated. What may be a clan name is also often included, enclosed within an inscribed notched square of uncertain meaning but now called a *ya-hsing*. The common addition by early Chou times of the phrase "May sons and grandsons forever treasure and use it" provides evidence that most vessels were made originally for use in temple sacrifices rather than for burial, but other vessels, poorly cast and inscribed with posthumous ancestral names of the newly deceased, were clearly intended for the tomb.

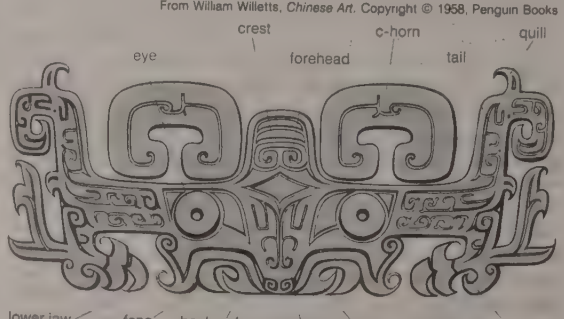
The right to cast or possess these vessels was probably originally confined to the royal house itself but later was bestowed upon local governors set up by the ruler; still later, in the Chou dynasty, the right was claimed by rulers of the feudal states and indeed by anyone who was rich and powerful enough to cast his own vessels.

Bronze vessel types

The vessel types are known today either by names given them in Shang or Chou times that can be identified in contemporary inscriptions, such as the *li, ting,* and *hsien,* or by names, such as *yu, chia,* and *kuang,* given them by later Chinese scholars and antiquarians. The vessels may be grouped according to their presumed function in sacrificial rites. For cooking food the main types are the *li,* a round-bodied vessel with a trilobed base extending into three hollow legs; its cousins, the *ting,* a hemispheric vessel on three solid legs, and *fang-ting,* a square vessel standing on four legs; and the *hsien,* or *yen,* a steamer consisting of a bowl placed above a *li* tripod, with a perforated grate between the two. For offering food, the principal vessel was the *kuei,* a bowl placed on a ring-shaped foot, like a modern-day wok. The word *tsun* embraces wine containers of a variety of shapes. Among vessels for heating or offering wine are the *yu,* a covered bucket with swing handle; the *chia,* a round tripod or square quadruped with a handle on the side and raised posts with caps rising from its rim; the related *chüeh,* a smaller beaker on three legs, with an extended pouring spout in front, a pointed tail in the rear, a side handle, and posts with caps; the *ho,* distinguished by its cylindrical pouring spout; the *kuang,* resembling a covered gravy boat; and the elegant trumpet-mouthed *ku.* Vessels for ablutions include the *p'an,* a large, shallow bowl. The shapes of the round-bodied vessels were often derived from earlier pottery forms; the square-section vessels, with flat sides generally richly decorated, are thought to derive from boxes, baskets, or containers of carved wood or bone.

Other objects connected with the rites were bronze drums and bells. Weapons and fittings for chariots, harness, and

From William Willetts, *Chinese Art*. Copyright © 1958, Penguin Books



T'ao-t'ieh mask from a first-phase *ting*, 13th–10th centuries BC.

other utilitarian purposes also were made of bronze.

Bronze vessels were cast not by the lost-wax process (using a wax mold), as formerly supposed, but in sectional molds, quantities of which have been found at Shang sites. In this complex process, which reflects the Chinese early mastery of the ceramic medium, a clay model of the body is built around a solid core representing the vessel's interior; clay molding is used to encase the model, then sliced into sections and removed; the model is eliminated; the mold pieces are reconstructed around the core, using metal spacers to separate mold and core; molten bronze is poured into the hollow space. Legs, handles, and appended sculpture are often cast separately and integrated in a later, lock-on pour. Surface decoration may be added to the model surface before the mold is applied, requiring a double-transfer from clay to clay to metal, or added in reverse to the mold surface after its removal from the model, with an incised design on the mold yielding a raised design on the metal surface. Ritual vessels range from about 15 centimetres to over 130 centimetres in height with weights up to 875 kilograms (1,925 pounds). The intricacy and sharpness of the decoration shows that by the end of the 2nd millennium BC the art of bronze casting in China was the most advanced in the world.

"Shaman figure" cast on a ceremonial bronze drum (Style IV) rubbing, *c.* 12th century BC, Shang dynasty. In the Sen-oku Hakko kan, Sumitomo Collection, Kyōto, Japan.

The *t'ao-t'ieh*

While many Shang ritual bronzes are plain or only partly ornamented, others are richly decorated with a variety of geometric and zoomorphic motifs, and a small number take the form of a bird or animal. The dominating motif is the *t'ao-t'ieh,* seen either as two stylized creatures juxtaposed face-to-face or as a single creature with its body splayed out on both sides of a masklike head. The term *t'ao-t'ieh* first appeared in the late Chou and is perhaps related to eclipse mythology and the idea of renewal. Sung dynasty antiquarians offered the unlikely interpretation that it represented a warning against gluttony. Alternative modern suggestions are that it was a fertility symbol like the later Chinese dragon, bestowing longevity on the ruling clan; that it was a fierce spirit which protected the rites and the participants from harm; that it embodied a variety of creatures related to the ceremonial sacrifices; that it was totemic or related to shamanic empowerment; or that its dual structure represented the inseparable forces of creation and destruction. Other creatures on the bronzes are the *k'uei* (each like half of the doubled *t'ao-t'ieh*), tiger, cicada, snake, owl, ram, and ox. In later times, the tiger represented nature's power, the cicada and snake symbolized regeneration, the owl was a carrier of the soul, and the ram and ox were chief animals of ancestral sacrifices. It is not known whether these meanings were attached to the creatures on Shang bronzes, for no Shang writing addresses the issue, but it seems likely that they had a more than purely decorative purpose. There is no suggested environmental setting for these creatures. The human figure appears only rarely in Shang bronzes, usually in the grasp of these powerful zoomorphic creatures.

Evolution of the Shang style

The art of the Shang bronzes evolved from technically simple, albeit sometimes quite elegant, thinly cast vessels, clearly revealing ceramic prototypes. It reached a climax of sculpturesque monumentality at the end of the dynasty, reflecting a long period of peace and stability at An-yang. In the early 1950s the scholar Max Loehr identified five phases or styles in the evolution of Shang bronze surface decor and casting techniques. The thin-walled vessels of Style I typically carry a narrow register of zoomorphic motifs that are more abstract in appearance than motifs of later times; the motifs are composed of thin, raised lines created by incision on the production molds. Style II zoomorphic forms are composed of broad, flat bands in narrow horizontal registers, incised on the model, often on a raised band of ceramic appliqué. In Style III, dense curvilinear designs derived from those of the previous phase begin to cover much of the surface of an increasingly thick-walled vessel, and the zoomorph becomes increasingly difficult to discern. The main zoomorphic motifs of Style IV, although flush to the surface of the vessel (ex-

Ceremonial bronze *lei* (Style III), *c.* 13th century BC, Shang dynasty. In the Palace Museum, Peking. Height 52 cm.

clusive of appended heads, handles, and fully sculptural attachments), become clearly distinguishable as set against a dense spiral background known as "thunder pattern" (*lei-wen*); in this phase, with similar spirals placed sparsely over the zoomorph, which itself is constructed from the same linear vocabulary, an intricate decorative system of interactive forms, rich in philosophical implications, begins to reach maturity. In Style V, the main motifs are set forth in increasingly bold plastic relief through the use of ceramic appliqué upon the model. Style I bodily form clearly reveals conceptualization derived from ceramics, while Style V vessels fully utilize the sculpturesque possibilities of the molded-bronze technology. Styles I and II appear at Cheng-chou; Style III appears at both Cheng-chou and early An-yang; and Styles IV and V are found in the An-yang period only. Pre-Style I vessels, ceramic in form, thin-walled, and with little or no surface decor, have been found at Erh-li-t'ou near Lo-yang, demonstrating early Shang or even Hsia origins.

Development of pottery glazes

Ceramics, jade, and lacquer. The Shang dynasty saw several important advances in pottery technology, including the development of a hard-bodied, high-fire stoneware and pottery glazes. A small quantity of stoneware is covered with a thin, hard, yellowish green glaze applied in liquid form to the vessel. Shang potters also developed a fine soft-bodied white ware, employing kaolin (later used in porcelain); this ware was probably for ceremonial use and was decorated with motifs similar to those on the ritual bronzes. Much cruder imitations of bronze vessels also occur in the ubiquitous gray pottery of the Shang dynasty.

In the Shang dynasty, and particularly at An-yang, the craft of jade carving made a notable advance. Ceremonial weapons and fittings for bronze weapons were carved from jade; ritual jades included the *pi, ts'ung,* and symbols of rank. Plaques and dress ornaments were carved from thin slabs of jade, but there are also small figurines, masks, and birds and animals carved in the round, some of these perhaps representing the earliest examples of *ming-ch'i* ("spirit vessels"), artistic figures substituted for live victims buried in order to serve the deceased.

Coffins, chariots, furniture, and other objects found in Shang tombs were often lacquered, and lacquer was used to fix inlays of shell and coloured stone. Small decorative and functional objects such as hairpins, finials, buttons, and knife handles were often fashioned of bone or ivory, sometimes inlaid with chips of turquoise.

Chou dynasty (11th century–255 BC). The arts of the Chou dynasty, the longest in Chinese history, reflect the profound changes that came over Chinese society during nearly 800 years. The first Chou rulers took over the Shang culture to the extent that the earliest bronze vessels bearing Chou inscriptions might, from their style, have been made in the Shang dynasty. The Chou kings parceled out their expanding territory among feudal lords, each of whom was free to make ritual objects for his own court use. As the feudal states rose in power and independence, so did the central Chou itself shrink, to be further weakened by the eastward shift of the capital from sites in the Wei River valley near modern-day Sian to Lo-yang in 771 BC. Thereafter, as the Chou empire was broken up among rival states, many local styles in the arts developed. The last three centuries of the Chou dynasty, known as the Warring States period, saw a flowering of the arts in many areas. The breakdown of the feudal hegemony, the growth of trade between the states, and the rise of a rich landowning and merchant class all brought into existence new patrons and new attitudes that had a great influence on the arts and crafts.

Architecture. Remains of a number of Chou cities have been discovered, among them capitals of the feudal states. They were irregular in shape and surrounded by walls of rammed earth. Some long defensive walls also have been located, the largest being one that protected the state of Ch'i from Lu to the south, stretching for more than 500 kilometres (300 miles) from the Huang Ho to the sea. Ch'u had a similar wall along its northern frontier.

Foundations of a number of palace buildings have been found in the cities, including, at Hui-hsien, the remains of a hall 26 metres (85 feet) square, which was used for ancestral rites in connection with an adjacent tomb—an arrangement that became common in the Han dynasty. An important late Chou structure used for the conduct of state rituals was the Ming-t'ang ("Spirit Hall"), discussed in Chou literature but not yet known through excavations. Late Chou texts also describe platforms or towers, *t'ai,* made of rammed earth and timber and used as watchtowers, as treasuries, or for ritual sacrifices and feasts, while pictures engraved or inlaid on late Chou bronze vessels show two-story buildings used for this type of ritual activity. Some of these multistory buildings are now understood, through modern excavations of two- and three-story Ch'in and Han palaces and of state ritual halls at Hsien-yang, Sian, and Lo-yang, to have been constructed around a large, raised pounded-earth core that structurally supported upper building levels and galleries and into which lower-level chambers were inserted.

Multistory buildings

The origins of the Chinese bracketing system also are found on pictorial bronzes, showing a spreading block (*tou*) placed upon a column to support the beam above more broadly, and in depictions of curved arms (*kung*) attached near the top of the columns, parallel to the building wall, extending outward and up to help support the beam; however, the block and arms were not yet combined to create traditional Chinese brackets (*tou-kung*) or to achieve extension forward from the wall. Roof tiles replaced thatch before the end of the Western Chou (771 BC), and bricks have been found from early in the Eastern Chou.

Ritual bronzes and related works. The ritual bronzes of the early Hsi (Western) Chou continued the late An-yang tradition; many were made by the same craftsmen and by their descendants. Even in the predynastic Chou period, however, new creatures had appeared on the bronzes, notably a flamboyant long-tailed bird that may have had totemic meaning for the Chou rulers, and flanges had begun to be large and spiky. By the end of the 9th century, moreover, certain Shang shapes such as the *chüeh, ku,* and *kuang* were no longer being made, and the *t'ao-t'ieh* and other Shang zoomorphs had been broken up and then dissolved into volutes or undulating meander patterns encircling the entire vessel, scales, and fluting, with little apparent symbolic intent.

From the outset of Chou rule, vessels increasingly came to serve as vehicles for inscriptions that were cast to record events and report them to ancestral spirits. An outstanding example, excavated near Sian in 1976, was dedicated by a Chou official who apparently had divined the date for the successful assault upon the Shang and later used his reward money to have the bronze vessel cast. By late Chou times, a long inscription might have well over 400 characters.

Vessel shapes, meanwhile, had become aggressive or heavy and sagging, and the quality of the casting is seldom as high as in the late Shang. These changes, completed by the 8th century BC, mark the middle Chou phase of bronze design.

Bronzes of the Eastern Chou period

The bronzes of the Tung (Eastern) Chou period, after 771 BC, show signs of a gradual renaissance in the craft and much regional variation, which appears ever more complex as more Eastern Chou sites are unearthed. Vessels from Hsin-cheng in Honan (8th to 6th century BC) reveal a further change to more elegant forms, often decorated with an allover pattern of tightly interlaced serpents. The aesthetic tendency toward elaboration was given further stimulus by the introduction of the lost-wax method of production (by the late 7th century BC), leading quickly to zealous experiments in openwork design that are impressive technically though heavy in appearance and gaudy in effect. The style of bronzes found at Li-yü in Shansi (*c.* 6th–5th century BC) is much simpler, more compact, and unified; the interlaced and spiral decoration is flush with the surface. Thereafter, until the end of the dynasty, the bronze style became increasingly refined; the decoration was confined within a simpler contour, the interlacing of the Hsin-cheng style giving way to the fine, hooked "comma pattern" of the vessels of the 5th and 4th centuries BC. By this time, bronze decor had come under the influence of textile patterns and technique, particularly embroidery, as well as of lacquer decor, suggesting

the decline from primacy of the bronze medium. Bronzes thus decorated have been found chiefly in the Huai River valley.

Bronze bells are exemplified by an orchestral set of 64 bells, probably produced in Ch'u and unearthed in 1978 from a royal tomb of the Tseng state, at Lei-ku-tun near Sui-hsien in Hupeh province. The bells were mounted on wooden racks supported by bronze human figurines. They are graded in size (from about 20 to 150 centimetres in height) and tone (covering five octaves), and each is capable of producing two unrelated tones according to where it is struck. Gold-inlaid inscriptions on each bell present valuable information regarding early musical terms and performance, while a 65th bell is dedicated by inscription from the king of Ch'u to Marquis I of Tseng, the deceased, and bears a date equivalent to 433 BC.

Finally, in vessels from the rich finds at Chin-ts'un near Lo-yang, all excrescences are shorn away; the shapes have a classic purity and restraint, and the decoration consists of geometric patterns of diagonal bands and volutes. The taste of the new leisured class is shown in objects that were not merely useful but finely fashioned and beautiful in themselves: ritual and domestic vessels, weapons, chariot and furniture fittings, ceremonial staff ends, bracelets, and the backs of mirrors. Monster masks attaching ring handles are reminiscent of the Shang *t'ao-t'ieh,* the first sign of a deliberate archaism that from time to time thenceforward gave a special flavour to Chinese decorative art.

The wealth and sophistication of late Chou culture is shown by exquisite craftsmanship, while the new techniques of cast openwork and many of the works executed with inlays of gold, silver, jade, glass, and semiprecious stones also indicate the increasing commercial interaction and artistic fascination of the Chinese with the tribal peoples to their north. Bronze garment hooks worn at the shoulder were often fashioned in the form of animals, reflecting the artistic style of China's nomadic neighbours, who through the Eastern Chou and Han dynasties exerted pressure on its northern frontiers and who both influenced and were influenced by Chinese culture in this period.

Bronze objects

Bronze mirrors were used in ancient China not only for toiletry but also as funerary objects, in accordance with the belief that a mirror was itself a source of light and could illuminate the eternal darkness of the tomb. A mirror also was thought of as a symbolic aid to self-knowledge. Chinese mirrors are bronze disks polished on the face and decorated on the back, with a central loop handle or pierced boss to hold a tassel. The early ones were small and worn at the girdle; later they became larger and were often set on a stand. A bronze disk found in a tomb at An-yang may have been a mirror. There is less doubt about the small disks from an 8th-century-BC tomb at Shang-ts'un-ling in Honan, believed to be the earliest mirrors yet found in China. Mirrors, however, were not widely used until the 4th and 3rd centuries BC. Shou-chou, in the state of Ch'u, was a centre for the manufacture of late Chou mirrors.

Sculpture. Chou sculpture, like that of the Shang, is typically small in scale and occurs most frequently in the medium of sculpturesque ritual bronze vessels. Examples from the middle Chou period are usually stiffly formal, but the forceful spatial rendering and emergent naturalism characteristic of Ch'in and early Han dynasty sculpture and seen in a massive late 3rd-century-BC inlaid bronze rhinoceros from Hsing-p'ing, Shensi province, had already appeared by the Warring States era. Inlaid bronze sculpture from the northeastern state of Chung-shan (late 4th century BC) reveals the influence of neighbouring nomadic art, and, if not as fully naturalistic, these works are nonetheless remarkably dynamic and alert, one notable example depicting a tiger capturing a hapless deer. No less fierce and even more bizarre are some of the lacquered sculptures from the southern state of Ch'u, such as the monstrous creature with real deer horns, bulging eyes, and long tongue devouring a snake, from about the 3rd century BC, excavated at Hsin-yang in Honan province. Simple pottery grave figurines also have been found at late Chou sites in northern China; and attenuated, formalized wooden figurines of servants and attendants, with details of dress painted on them, have been found in graves of the state of Ch'u.

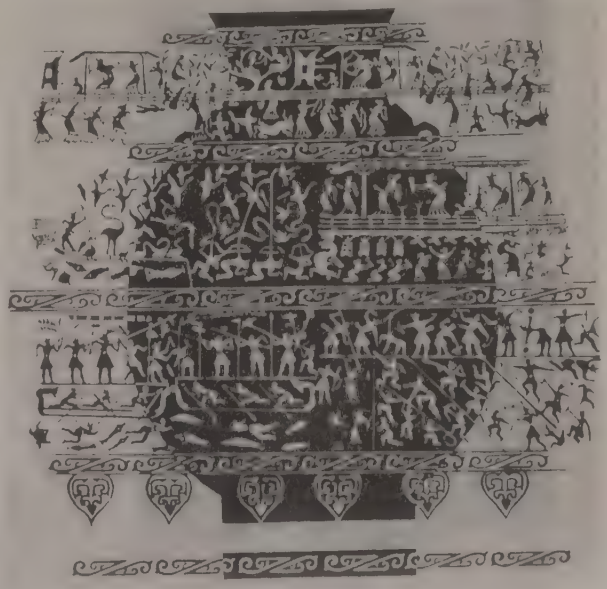
Painting and pictorial arts. Practically nothing survives of Chou painting, although from literary evidence it seems that the art developed considerably, particularly during the period of the Warring States. Palaces and ancestral halls were decorated with wall paintings. The most significant development of the late Chou, and among the most revolutionary of all moments in Chinese art, was the emergence of a representational art form, departing from the ritualized depiction of fanciful and usually isolated creatures of the Shang and early to middle Chou. In decorating ceremonial objects, artists began to depict the ceremonies themselves, such as ancestral offerings in temple settings, as well as ritual archery contests (important in the recruitment and promotion of officials), agriculture and sericulture, hunting, and the waging of war—all activities vital to a well-ordered state. Such representations were cast with gold or silver inlay or engraved onto the sides of bronze vessels, most notably the *hu,* where all these themes might be combined on a single vessel. This conceptual transformation began by the late 6th century BC, at about the same time that Confucius and other philosophers initiated humane speculation on the nature of statecraft and social welfare.

Emergence of representational art

The early representation of landscape, indicated only crudely on bronzes, appears in more sophisticated fashion on embroidered textiles of the 4th–3rd centuries BC from such south-central Chinese sites as Ma-shan, near Chiangling in the state of Ch'u (modern Hupeh province). There, as in Han dynasty art to follow, landscape is suggested by rhythmic lines, which serve as mountain contours to spatially organize a variety of wild animals in front and back and which, while structurally simple, convey in linear fashion a sophisticated concept of mountain landscape as fluid, dynamic, and spiritual.

Some of these motifs and, perhaps, the early treatment of landscape itself may derive in both theme and style from foreign sources, particularly China's northern nomadic neighbours. Those scenes concerned with ceremonial archery and ritual offerings in architectural settings, sericulture, warfare, and domestic hunting, however, seem to be essentially Chinese. These renditions generally occur with figures in flattened silhouette, spread two-dimensionally and evenly over most of the available pictorial surface. But, by the very late Chou, occasional examples, such as the depiction of a mounted warrior contending with a tiger, executed in inlaid gold and silver on a bronze mirror

Wang Lu/ChinaStock Photo Library



Drawing of ancestral offering scenes (ritual archery, sericulture, hunting, and warfare) cast on a ceremonial bronze *hu,* 6th–5th century BC, Chou dynasty. In the Palace Museum, Peking.

from Chin-ts'un (*c.* 3rd century BC, Hosokawa collection, Tokyo), suggest the emerging ability of artists to conceive of two-dimensional images in terms of implied bulk and spatial context.

Early paintings on silk

The few surviving Chou period paintings on silk—from about the 3rd century BC, the oldest in all East Asia—were produced in the state of Ch'u and unearthed from tombs near Ch'ang-sha. One depicts a woman, perhaps a shamaness or possibly the deceased, with a dragon and phoenix; one depicts a gentleman conveyed in what appears to be a dragon-shaped boat; and a third, reported to be from the same tomb as the latter, is a kind of religious almanac (the earliest known example of Chinese writing on silk) decorated around its border with depictions of deities and sacred plants.

Jade. In the Chou, production of jade *pi, ts'ung,* and other Shang ritual forms was continued and their use systematized. Differently shaped sceptres were used for the ranks of the nobility and as authority for mobilizing troops, settling disputes, declaring peace, and so on. At burial, the seven orifices of the body were sealed with jade plugs and plaques. Stylistically, Chou dynasty jades first continued Shang traditions, but then, just as the bronzes did, they turned toward looser, less systematic designs by middle Chou times, with zoomorphic decor transformed into abstract meander patterns. This breakdown of formal structure continued to the end of the dynasty.

The introduction of iron tools and harder abrasives in the Eastern Chou led to a new freedom in carving in the round. Ornamental jades, chiefly in the form of sword and scabbard fittings, pendants, and adornment for the clothing, were fashioned into a great variety of animals and birds, chiefly from flat plaques no more than a few millimetres thick.

Glass. Glass was already in use in China in the Western Chou period, attested by beads found in tombs in Sian and Lo-yang of the 9th and 8th centuries BC. In the Eastern Chou it was sometimes used as a cheap substitute for jade *pi* disks and sword fittings and as an inlay in garment hooks and various ornamental objects. While some glass beads were certainly imported from western Asia, the craft of glassmaking may have begun in China independently as a by-product of the manufacture of pottery glaze.

Ceramics. Early Western Chou pottery, like the bronzes, continued the Shang tradition at a somewhat lower technical level, and the soft white Shang pottery disappeared.

The Metropolitan Museum of Art, New York City, on loan from the People's Republic of China; photograph by Seth Joel

Kneeling archer from the tomb of Emperor Shih Huang-ti, Lin-t'ung, near Sian, Shensi province, *c.* 210 BC, Ch'in dynasty. Terracotta with traces of paint. In the Museum of Ch'in Dynasty Terracotta Warriors and Horses, Lin-t'ung. Height 1.2 m.

Stemmed offering dishes, *tou,* were made in a hard stoneware dipped or brushed over with a glaze ranging from gray to brownish green. The fact that some of the richest finds of high-fired glazed wares have been made not in Honan but at Yi-ch'i in Anhwei shows that the centre of advance in pottery technology was beginning to move, with the growth of population, to the lower Huai and Yangtze valleys. Crude attempts also were made to give pottery the appearance of bejeweled metal by covering *tou* stands with lacquer inlaid with shell disks.

In the second half of the dynasty the range of pottery types and techniques was greatly extended. A low-fired pottery was produced in Honan primarily for burial. Some of it is white, and some is covered with slip, or liquid clay, and painted, reviving an ancient northern China tradition. At Hui-hsien has been found a soft-bodied, black burnished ware, sometimes decorated with scrolls and geometric motifs scratched through the polished surface. In the period of the Warring States, a soft earthenware covered with green lead glaze was made in northern China for burial. In the lower Yangtze valley an almost porcelaneous stoneware was developing, covered with a thin feldspathic glaze, the ancestor of the celadon glaze of the T'ang dynasty and later. Another technique, which appears in the glazed wares of Chekiang and Kiangsu and was to persist in the southern pottery tradition for many centuries, was the stamping of regular, repeated motifs over the surface of the vessel before firing.

Development of an almost porcelaneous stoneware

Ch'in (221–206 BC) and Han (206 BC–AD 220) dynasties. In 221 BC the ruler of the feudal Ch'in state united all China under himself as Ch'in Shih Huang-ti ("First Sovereign Emperor of Ch'in") and laid the foundation for the long stability and prosperity of the succeeding Han dynasty. His material accomplishments were the product of rare organizational genius, including centralizing the Chinese state and its legal system, unifying the Chinese writing script and its system of weights and measures, and consolidating many of the walls of northern China into an architectural network of beacon towers able to spot any suspicious military movement and relay messages across the territory in a single day. However, his means were brutal and exhausted the people, and the dynasty failed to survive his early death.

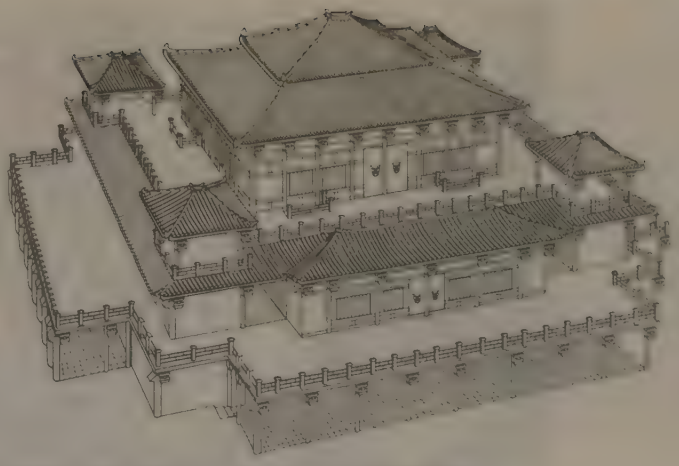
The Hsi (Western) Han (206 BC–AD 25), with its capital at Ch'ang-an (near modern Sian), reached a climax of expansive power under Wu-ti (ruled 141/40–87/86 BC), who established colonies in Korea and Indochina and sent expeditions into Central Asia, which both made Chinese arts and crafts known abroad and opened up China itself to foreign ideas and artistic influences. After the period of the usurping Hsin dynasty (AD 9 to 25), the Tung (Eastern) Han, with its capital at Lo-yang, recovered something of the dynasty's former prosperity but was increasingly beset by natural disasters and rebellions that eventually brought about its downfall. The art of the Han dynasty is remarkable for its variety and vigour, the product of foreign contacts, of a national unity in which many local traditions flourished, and of the patronage of a powerful court and the new, wealthy landowning and official classes.

Architecture. While little remains except walls and tombs, much can be learned about Han architecture from historical writings and long descriptive poems, *fu.* This was an era of great palace buildings. The first Ch'in emperor undertook the building of a vast palace, the A-fang or O-pang, whose main hall was intended to accommodate 10,000 guests in its upper story. He also copied the palaces and pavilions of each of the feudal lords he had defeated; these buildings stretched more than seven miles along the Wei River and were filled with local lords and women captured from the different states.

The first emperor's tomb was part of a city of the dead that covered nearly 2 square kilometres (0.75 square mile) and was surrounded by double walls, with numerous gates, corner towers, and a ceremonial palace. The mausoleum itself was surmounted by an artificial mound, a feature not known in the Shang or early Chou and first found among the 4th–3rd-century-BC tombs near Chiang-ling in Hupeh province. About 43 metres high, this tumulus was shaped like a triple-layered truncated pyramid symbolizing

heaven, man, and earth. The tomb, which has not yet been excavated, reportedly featured a large chart of the heavens painted on its domed vault and a three-dimensional representation of the earth below, with rivers of liquid mercury driven by mechanical contrivances. Excavations around the tomb have uncovered a large protective "spirit army" of some 7,000 life-size terra-cotta figurines, along with 400 horses and 100 chariots, placed in battle formation in a series of pits beneath the nearby fields. Molded in separate sections, assembled, then fully painted, these warrior figures are executed in minute and realistic detail and provide evidence of an early naturalistic sculptural tradition scarcely imagined before their discovery in 1974. For the heads, up to 30 different models were used, and each was hand-finished to give further variety. Excavated later, in 1982, was a pair of precisely engineered bronze replicas of the Imperial chariot (104 centimetres high, with considerable gold and silver inlay), each with charioteer and four horses, possibly indicating the presence of a still larger underground stable of such figures.

Terra-cotta "spirit army"



Reconstructive elevation of the Ming-t'ang state ritual hall, Ch'ang-an (Sian), Shensi province, *c.* 1st century BC, Han dynasty.

The main audience hall of the Western Han Wei-yang palace was said to have been about 120 metres long by 35 metres deep, possibly smaller than its largest Ch'in predecessor yet much larger than its equivalents in the Peking palace today. From the Chou dynasty through the Yüan, no architectural structure called forth more intense consideration than the so-called Ming-t'ang ("Spirit Hall"), the predecessor of Peking's Temple of Heaven. The site of the Han ritual hall, in the southern suburbs of Han dynasty Ch'ang-an, was excavated in 1956–57. Translating traditional ritual values into symbolic architecture, the Ming-t'ang was surrounded by an outer circular moat and set on a circular foundation (the two circles together forming a disk, or *pi,* symbolic of heaven) and was further enclosed within an intermediate rectilinear colonnade (symbolic of earth). The three-story hall itself (the number three signifying heaven, man, and earth) was built around a raised earthen core. It is thought to have been a composite ritual structure that included a royal academy on the first floor; a second floor divided into nine zones, corresponding to the four seasons and the "five phases" theory of change, with five inner shrines and with outer spaces for monthly ritual offerings; and a third-floor central hall surrounded by a terrace (*ling-t'ai,* or "spirit platform") for observation of the heavens and regulation of the calendar.

The Han palaces were set about with tall timber towers (*lou*) and brick or stone towers (*t'ai*) used for a variety of purposes, including the display and storage of works of art. Ceramic representations of Han architecture provide the first direct evidence of true bracketing, with simple brackets projecting a single step forward (and sometimes several steps upward) from the wall in order to support the roof projection.

Han tombs

Han tombs are among the most elaborate ever constructed in China. In some localities they are of timber, but more often they are of brick or stone, divided into several chambers, and covered with a corbeled vault or more rarely a true arched vault. The tombs of the Han emperors were enclosed in gigantic earth mounds that are still visible today, but some royal tombs began the later practice of burial in hollowed-out natural hills. Many Han tombs were decorated with wall paintings, with more permanent and expensive stone reliefs, or with stamped or molded bricks.

The most remarkable excavated tomb of the period belonged to the wife of a mid-level aristocrat, one of three family tombs of the governor of Ch'ang-sha found in a suburb of that southern city, Ma-wang-tui, and dating from 168 BC or shortly after. Small in scale but richly equipped and perfectly preserved, the wooden tomb consists of several outer compartments for grave goods tightly arranged around a set of four nested lacquered coffins. An outer layer of sticky white kaolin clay prevented moisture from penetrating the tomb, and an inner layer of charcoal fixed all the available oxygen within a day of burial, so the deceased (Hsin Chui, or Lady Tai, the governor's wife) was found in a near-perfect state of preservation. Included among the grave goods, which came with a written inventory providing contemporaneous terminology, are the finest caches yet discovered of early Chinese silks (gauzes and damasks, twills and embroideries, including many whole garments) and lacquerwares (including wood-, bamboo-, and cloth-cored examples), together with a remarkable painted banner that might have been carried by the shaman in the funerary procession (see below).

Painting and related arts. Literature and poetry indicate that the walls of palaces, mansions, and ancestral halls were plastered and painted. Themes included figure subjects, portraits, and scenes from history that had an ethical or didactic purpose. Equally popular were themes taken from folk and nature cults that expressed the beliefs of popular Taoism. The names of the painters are generally not known. Artists were ranked according to their education and ability from the humble craftsmen painters (*hua-kung*) up to the painters-in-attendance (*tai-chao*), who had high official status and were close to the throne, a bureaucratic system that lasted into the Ch'ing dynasty.

In addition to wall paintings, artists painted on standing screens, used as room dividers and set behind important personages, and on long rolls of silk. Paper was invented in the Han dynasty, but it is doubtful whether it was much used for painting before the 3rd or 4th century AD.

Han tomb paintings

The most important painted tombs have been found at Lo-yang, where some are decorated with the oldest surviving historical narratives (1st century BC); at Wang-tu in Hopeh (Eastern Han), where they are adorned with figures of civil and military officials; and at Liao-yang in Liaoning, where the themes include a feasting scene, musicians, jugglers, chariots, and horsemen. The celebrated bricks taken from a tomb shrine of the Eastern Han (now in the Museum of Fine Arts, Boston) depict gentlemen in animated conversation, elegant and individualized and rendered with a sensitive freedom of movement.

Funerary slabs also reflect the variety of Han pictorial art. The most famous are those from tomb shrines of the Wu family at Chia-hsiang in Shantung, dated between about AD 147 and 168. The subjects range from the attempted assassination of the first Ch'in emperor to feasting and mythological themes. Although they are depicted chiefly in silhouette with little interior drawing, the effect is lively and dramatic. These well-known works have been generally taken as representative of Han painting style since their discovery in 1786. They are now understood, however, to be very conservative in style, even archaistic, perhaps with the intent of advertising the sponsoring family's chaste attachment to the pure and simple virtues of past times. A far earlier painting, a funerary banner from about 168 BC, excavated in 1972 at Ma-wang-tui, reveals how much more sophisticated early Han and even late Chou painting must have been. Painted with bright, evenly applied mineral pigments and fine, elegant brush lines on silk, the banner represents a kind of cosmic array, with separate scenes of a funerary ceremony, the underworld, and the ascent of the deceased (the Lady Tai mentioned

Rubbing of a stone relief from the tomb shrine (*tz'u*) of Wu Liang, Shantung province, Eastern Han dynasty (AD 25–220). In the Department of Art and Archaeology, Princeton University, New Jersey, U.S. 70 cm × 146 cm.

above) to a heavenly setting filled with mythic figures. It contains stylistic features not previously seen before the 4th century AD, creating spatial illusion through foreshortening, overlapping, and placement upon an implied ground plane, as well as suggesting certain lighting effects through contrasting and modulated colours.

Han landscape painting

Han landscape painting is well represented by the lacquer coffins of Lady Tai at Ma-wang-tui, two of which are painted with scenes of mountains, clouds, and a variety of full-bodied human and animal figures. Two approaches are used: one, more architectonic, uses overlapping pyramidal patterns that derive from the bronze decor of the late Chou period; the other continues the dynamic linear convention already noted on the embroidered textiles from Chiang-ling, in the Warring States period, as well as on late Chou painted lacquers, on inlaid bronze tubes used as canopy fittings for chariots, and on woven silks found at Noin-ula, in Mongolia. Elsewhere, in the late Han, a new feeling for pictorial space in a more open outdoor setting appeared on molded bricks decorating tombs near Ch'eng-tu; these portrayed hunting and harvesting, the local salt-mining industry, and other subjects.

Lacquer. By the Han dynasty, lacquer production was chiefly carried on at Ch'ang-sha and in four regional factories in Shu (modern Szechwan) under government control. In addition to the fine lacquerwares excavated from tombs in Ch'ang-sha, splendid products of the Szechwan workshops, bearing inscriptions dated between 85 BC and AD 71, have been found in tombs of Chinese colonists at Lo-lang (Nangnang) in North Korea, and pieces of Han lacquerware have been found as far afield as northern Mongolia and Afghanistan.

The different stages of Han lacquer manufacture were divided among a number of specialized craftsmen. The *su-kung,* for example, prepared the base, which might be of hemp cloth, wood, or bamboo basketwork; after priming, the base was covered with successive layers of lacquer by the *hsiu-kung.* The top layer, applied by the *shang-kung,* was polished and so prepared for the painter, *hua-kung,* who decorated it. Others might inlay the design or engrave through the top coating to another colour beneath it, add gilding, and write or engrave an inscription. A wine cup found at Lo-lang bears an inscription giving its capacity, the names of the people concerned in its manufacture, a date equivalent to AD 4, and place of origin, the "Western Factory" in Shu Commandery.

Among the most celebrated examples of Han lacquer painting is a basket found at Lo-lang (National Museum, Seoul), decorated with 94 small figures of paragons of filial piety, virtuous and wicked rulers, and ancient worthies.

Development of silk weaving into a major industry

Textiles. Silk weaving became a major industry and one of China's chief exports in the Han dynasty. The caravan route across Central Asia, known as the Silk Road, took Chinese silk to Syria and on to Rome. In the 4th century BC, the Greek philosopher Aristotle mentions sericulture on the island of Cos (Kos), but the art was evidently lost and reintroduced into Byzantium from China in the 6th century AD. Chinese textiles of Han date have been found in Egypt, in graves in northern Mongolia (Noin-ula), and at Lou-lan in Chinese Turkistan. Silk was used by Han rulers as diplomatic gifts and to buy off the threatening nomads, as well as to weaken them by giving them a taste of luxury.

Early Han textiles recovered from Ma-wang-tui show the further development of the weaving traditions already present at Ma-shan in the late Chou, including brocade and embroidery, gauze, plain weaves, and damasks. Later finds elsewhere, however, are limited chiefly to damasks, very finely woven in several colours with patterns that generally repeat about every five centimetres. These designs are either geometric, the zigzag lozenge being the most common, or consist of cloud or mountain scrolls interspersed with fabulous creatures and sometimes with auspicious characters. The rectilinear patterns were transmitted from woven materials to Lo-yang bronze mirrors and appeared in paintings on both lacquer and silk; and the curvilinear scroll patterns, which are not natural to weaving, were probably adapted for embroidery from the rhythmic conventions of lacquer painting, which also provided scroll motifs for inlaid bronzes and paintings on silk. Thus, there was an interaction among the various media of Han dynasty arts that accounts for their unity of style.

Sculpture. The Han dynasty saw the creation of the first major works of stone tomb sculpture in China. It is possible that the idea of a processional way leading to the tomb, lined with monumental stone carvings of animals and guardian figures, came to China through its new contacts with western and Central Asia. Thought to be the earliest such figures are a group from the tomb of Huo Ch'ü-ping, buried in 117 BC next to the tomb of Emperor Wu-ti, in whose name he won many battles of conquest in Central Asia. The best-known of these sculptures is a crude and static yet monumentally impressive horse standing over a trampled barbarian. The Chinese tomb sculptures that followed this early example never attained much more in the way of dynamic expression. Yet Han artists were capable of a far more mobile conception, as seen in the famous bronze "flying horse" from a 2nd-century-AD military tomb at Lei-t'ai near Wu-wei, Kansu province. This work represents the lively tradition of figural bronze and ceramic sculpture unearthed in vast quantities from Han tombs. Called *ming-ch'i* ("spirit vessels"), these sculptures were meant to function as the real objects they depict in the service of the deceased. The ceramic *ming-ch'i* include servants, guards, soldiers, dancers, jugglers, and acrobats, frequently modeled with all the vitality of a popular art; they give a vivid picture of daily life in the Han dynasty and represent Chinese sculpture at its very best. There also are models of farmhouses and multistoried towers, pigpens and duck ponds, cooking stoves, and a wide variety of food and wine vessels. Ceramic *ming-ch'i* are generally of low-fired earthenware, often covered with chalk or a white slip and then painted; the painted food and wine vessels often imitate both the shape and the scrolled decoration of inlaid bronze or painted lacquer vessels.

Ritual bronzes and mirrors. Already by late Chou times, the more expensive medium of lacquer was often used in place of bronze. Nevertheless, some bronze vessels were still made for sacrificial rites, and other bronze objects such as lamps and incense burners also were made for household use. The "hill censer" (*po-shan hsiang-lu*) was designed as a miniature, three-dimensional mountain of the immortals, usually replete with scenes of mythic combat between man and beasts suggesting the powerful forces of nature that only the Taoist adept could tame. Sacred vapours emanating from materials burned within were released through perforations in the lid (hidden behind the mountain peaks). Cosmic waters were depicted lapping at the base of the hills, conveying the sense of an island; and the whole was set on a narrow stem that thrust the mountain upward as if it were an axis of the universe. Such censers might have been used in ceremonial exorcism, in funerary rites associated with the ascent of the soul, or in other varieties of Taoist religious practice.

The "hill censer"

Some Han mirrors have astronomical or astrological patterns. The most elaborate, particularly popular during the Hsin dynasty (AD 9–25), bears the so-called TLV pattern. These angular shapes, ranged around the main band of decoration between a central square zone and the outer border band, are believed to be linked to a cosmological "chess" game called *liu-po;* the decoration also may include creatures symbolic of the four directions, immortals, and other mythical beings popular in Taoist folklore. Often the mirrors carry inscriptions, varying from a simple expression of good luck to a long dedication giving the name of the maker and referring to the Shang-fang or Imperial workshop. In the Eastern Han the Taoist elements dominated mirror design, which often includes the legendary Queen Mother of the West, Hsi Wang Mu, and her royal eastern counterpart, Tung Wang Kung. The coming of Buddhism at the end of the Han dynasty caused a decline in the use of cosmological mirrors. Mirror making, however, was revived in the T'ang dynasty.

Han glazed wares

Ceramics. Han glazed wares are chiefly of two types. Northern China saw the invention, presumably for funerary purposes only, of a low-fired lead glaze, tinted bottle-green with copper oxide, that degenerates through burial to an attractive silvery iridescence. High-fired stoneware with a thin brownish to olive glaze was still being made in Honan, but the main centre of production was already shifting to the Chekiang region, formerly known as Yüeh. Yüeh ware kilns of the Eastern Han, located at Te-ch'ing in northern Chekiang, produced a hard stoneware, often imitating the shapes of bronze vessels and decorated with impressed, bronzelike designs under a thin olive glaze. Other important provincial centres for pottery production in the Han dynasty were Ch'ang-sha (in Hunan province) and Ch'eng-tu and Chungking (in Szechwan province).

Three Kingdoms (220–280) and Six Dynasties (220–589). For 60 years after the fall of Han, China was divided among three native dynasties: the Wei in the north, Wu in the southeast, and Shu-Han in the west. It was briefly reunited under the Hsi (Western) Chin; but, in 311, Lo-yang and, in 316, Ch'ang-an fell to the invading Hsiung-nu, and before long the whole of northern China was occupied by barbarian tribes who set up one petty kingdom after another until, in 439, a Turkish tribe, the Toba, brought the region under their rule as the Pei (Northern) Wei dynasty. They established at P'eng-ch'eng (modern Ta-t'ung) in Shansi a capital that they populated by the forced immigration of tens of thousands of Chinese. The Chinese they recruited into their service civilized the Toba until they became completely Sinicized. In 495 the Wei moved their capital to Lo-yang in the heartland of ancient Chinese civilization, where they lost what little Turkish identity they still possessed. They were succeeded in 535 by other petty barbarian dynasties who held the north until the reunification of China in 581.

The barbarians adopted Buddhism as a matter of state policy, for Buddhism was an international religion with a concept of kingship that helped them to equate their earthly with their spiritual authority and thus to legitimize their control over the Chinese. Moreover, in the devastated land that was northern China in the 4th and 5th centuries, when the Confucian system was in ruins and Taoism a refuge for the few, the Buddhist doctrine of salvation through faith and good works acted as a powerful consoling and uniting force.

Buddhist missionaries and art came to Nanking by way of Indochina, but this cultural traffic did not become important before the 4th century. Although the rulers with few exceptions were weak, corrupt, or cruel and the court a maze of intrigue, it was chiefly in Nanking that the great poets, calligraphers, painters, and critics flourished, and they in turn greatly influenced the arts of the occupied north.

Architecture. After the fall of Lo-yang and Ch'ang-an, there was no more great city and palace building until

the Northern Wei moved their capital to Lo-yang in 495. There they constructed a city of great magnificence, sacked at their fall in 535. The main monuments of the 4th and 5th centuries were temples and monasteries. By the mid-6th century there were some 500 religious establishments in and around Lo-yang alone, about 30,000 in the whole of the northern realm.

Pagodas

Each Buddhist temple had its pagoda erected as a reliquary or memorial, and other pagodas dotted the city and the surrounding landscape. They have mostly disappeared, but one can get some idea of their form from reliefs at Yün-kang and from the earliest surviving pagodas at Nara in Japan. Based on an enlargement and refinement of the Han timber tower, or *lou*, they had up to 12 stories, with a projecting mast at the top ringed with metal disks. This mast was the only feature preserved from the Indian Buddhist burial or reliquary mound, the stupa, a hemispherical form that the Chinese rarely seem to have copied. The brick and stone pagodas, which were originally more Indian in form and were gradually Sinicized, are tiered structures with the stories marked by projecting string courses (horizontal bands) and architectural features borrowed from timberwork indicated in relief. The oldest surviving example is the Sung-yüeh Temple, a 12-sided stone pagoda on Mount Sung (*c.* 520–525) that is Indian in its shape and detail.

Sculpture. The earliest known Chinese Buddhist sculpture was made in the Eastern Han (at Ma-hao and P'eng-shan, in Szechwan, 2nd century AD). The first Buddhist images in gilt bronze were copies of icons brought to China from Central Asia, Afghanistan, and possibly India itself. Some are very clumsily modeled, which is not surprising when one considers that the Chinese craftsmen were copying an alien style and iconography. The finest, however, have a simple, compact charm, as can be seen in a seated Buddha (Asian Art Museum of San Francisco, The Avery Brundage Collection) copied from an Indian Gandhāra model. Bearing an inscription of 338, it is the earliest dated Chinese Buddha yet discovered.

Cave shrines

In the first centuries of Buddhist history in China, rock-cut cave temples and monastic cells rivaled timber-built courtyard temples in importance. In 460 a Chinese priest recommended to the Wei ruler that he should carve from a cliff face near the northern capital, Ta-t'ung, five huge images, dedicated to four of his Imperial predecessors and himself. These are caves XVI to XX at Yün-kang, cut in the 460s and 470s. The scale is heroic: the standing Buddha of cave XVIII and the seated Buddha of cave XX are each 14 metres high. The style is based on Central Asian models, squat in proportion and broad-shouldered, with large, square faces and staring eyes and drapery indicated in stylized repeated folds.

"Empress as Donor with Attendants," limestone relief with traces of colour, from Pin-yang Cave, Lung-men, Honan province, *c.* AD 522, Northern Wei dynasty. In The Nelson-Atkins Museum of Art, Kansas City, Mo., U.S. 1.93 m × 2.77 m.

The early work at Yün-kang represents the culmination of the first phase of Buddhist sculpture in China. "Paired" caves at Yün-kang (caves VI–XII), some of which were commissioned by subsequent rulers in honour of their parents, show a progressive change in style. This style developed into an entirely different second phase, which was flat and linear and which spread to the north from Nanking. The shift of the capital southward to Lo-yang in 494 marked the beginning of massive borrowing from southern culture, as, for example, in work begun at nearby Lung-men, where the Wei emperor commissioned the Pin-yang Cave, carved between 508 and 523. Here the second phase is fully mature. The figures are flattened, the angular body almost disappearing beneath a cascade of drapery and trailing scarves; the head is elongated, the eyes are half closed, and a gentle smile touches the lips. This ethereal style, which has been compared to that characteristic of Western Romanesque sculpture, shows the influence of the courtly figure painting in 5th-century Nanking, most clearly in panels in the Pin-yang Cave depicting the emperor and empress advancing in procession with their attendants. It has been suggested that the panels may have been inspired by southern paintings brought north, such as the transportable lacquer screens in southern court style dated 484 and found in the tomb of Ssu-ma Chin-lung at Ta-t'ung.

The second phase style is eloquently displayed in stone stelae (stone slabs or pillars that were used for votive or commemorative purposes) and gilt bronze altar groups of the 5th and 6th centuries. The stelae are carved in either of two styles: slablike monoliths with figures cut in the surface or leaf-shaped mandorlas with a group, generally the Buddha and bodhisattvas, standing out in high relief. Among the most beautiful of the gilt bronzes is an image of Śākyamuni (the historical Buddha) and Prabhūtaratna of 518 (in the Guimet Museum, Paris), which shows the attenuated linear style of the second phase carried almost to the point of mannerism.

Before 550 Buddhist sculpture began to undergo a further radical change. This new third phase style, by contrast with the second phase, is solid and dignified; the standing figures are rigidly frontal and columnar and the heads massive and erect. In the bodhisattva figures, thick strands of jewelry play over the surface, making a striking contrast to the severe folds of the clinging robes; some figures are more plastic and sculptural, reflecting the Indian influence

that was now once more penetrating into China, this time from the south, through new channels of trade and the many diplomatic and religious missions sent to Nanking by Linyi (Champa, now part of Vietnam) and Funan (approximately present-day Cambodia). From Nanking the new Indianized style spread to northern China, where it may be seen in the sculpture of the Northern Ch'i dynasty (550–577), and up the Yangtze River to Szechwan, where, at the Wan-fo Temple in Ch'eng-tu, there has been found a hoard of 6th- and 7th-century images, some of which are remarkably close to the Indian Gupta style. This third phase confrontation of Chinese and Indian art produced many styles, but at its best it attains a remarkable blend of surface richness and monumental grandeur. By the end of this phase, columnar rigidity began to give way to a more natural bearing of bodily weight, a swaying posture, and greater spatial extension (as seen in the Kuan-yin of about 570 in the Museum of Fine Arts, Boston), which became more fully developed in the Sui and T'ang dynasties.

Spread of the Indianized style

Painting. The breakdown of the Confucian system after the Han was reflected in painting and painting theory by an emphasis on Taoist and Buddhist themes and reasons for painting. This period saw the first activity by the courtier class, who painted as amateurs and who were far better remembered in the written record of the art than were their professional, artisan-class counterparts. Among the first named painting masters, Ts'ao Pu-hsing and Tai K'uei painted chiefly Buddhist and Taoist subjects. Tai K'uei was noted as a poet, painter, and musician and was one of the first to establish the tradition of scholarly amateur painting (*wen-jen hua*). He was also the leading sculptor of his day, almost the only instance in Chinese history of a gentleman who engaged in this craft.

The greatest painter at the southern court in this period was Ku K'ai-chih, an amateur painter from a family of distinguished Tung (Eastern) Wei dynasty scholar-officials in Nanking and an eccentric member of a Taoist sect. One of the most famous of his works (which survives in a T'ang dynasty copy in the British Museum) illustrates a 3rd-century didactic text "Nü-shih chen" ("Admonitions of the Court Instructress"), by Chang Hua. In this hand scroll, narrative illustration is bound strictly to the text (as if used as a mnemonic device): the advice to Imperial concubines to bear sons to the emperor, for instance, is accompanied by a delightful family group. The figures are slender and fairylike, and the line is fine and flows rhythmically. The roots of this elegant southern style, which then epitomized the highest Nanking court standard, can be traced back to Ch'ang-sha in the late Chou–early Han period, and it was later adopted as court style by the Northern Wei rulers (*e.g.*, at Lung-men) when they moved south to Lo-yang in 495. Ku K'ai-chih also was noted as a portraitist, and, among Buddhist subjects, his rendering of the sage Vimalakīrti became a model for later painters.

Ku K'ai-chih

The south saw few major painters in the 5th century, but the settled reign of Wu-ti in the 6th produced a number of notable figures, among them Chang Seng-yu, who seems to have combined realism with a new freedom in the use of the brush, employing dots and dashing strokes very different from the fine precision of Ku K'ai-chih.

While all the temples of the period have been destroyed, a quantity of wall painting survives at Tun-huang in northwestern Kansu in the Caves of the Thousand Buddhas, Ch'ien-fo Tung, where there are nearly 500 cave shrines and niches dating from the 5th century onward. Early Tun-huang paintings depict chiefly incidents in the life of the Buddha, the Jātaka (stories of his previous incarnations), and such simple themes as the perils from which Avalokiteśvara (Chinese: Kuan-yin) saves the faithful. In style they show a blend of Central Asian and Chinese techniques that reflects the mixed population of northern China at this time.

Painters practicing foreign techniques were active at the northern courts in the 6th century. Ts'ao Chung-ta painted, according to an early text, "after the manner of foreign countries" and was noted for closely clinging drapery that made his figures look as though they had been drenched in water. At the end of the 6th century, a painter from Khotan (Ho-t'ien), Wei-ch'ih Po-chih-na, was active at the Sui court; a descendant of his, Wei-ch'ih I-seng, painted frescoes in the temples of Ch'ang-an using a thick impasto (a thick application of pigment) and a brush line that was "tight and strong like bending iron or coiling wire." Those foreign techniques caused much comment among the Chinese but seem to have been confined to Buddhist painting and eventually were abandoned.

The beginning of aesthetic theory in China was another product of the spirit of inquiry and introspection that was abroad in these restless years. About AD 300 a long passionate poem, "Wen Fu" ("Rhymeprose on Literature") was composed by Lu Chi on the subject of artistic creation. Also from this period, the *Wen-hsin tiao-lung* ("Literary Mind and Carving of Dragons") by Liu Hsieh (*c.* 465–*c.* 522) has long remained China's premier treatise on aesthetics. It offers insightful consideration of a wide range of chosen topics, beginning with a discussion of *wen*, or nature's underlying pattern. Set forth as central to the mastery of artistic expression are the control of "wind" (*feng*, emotional vitality) and "bone" (*ku*, structural organization).

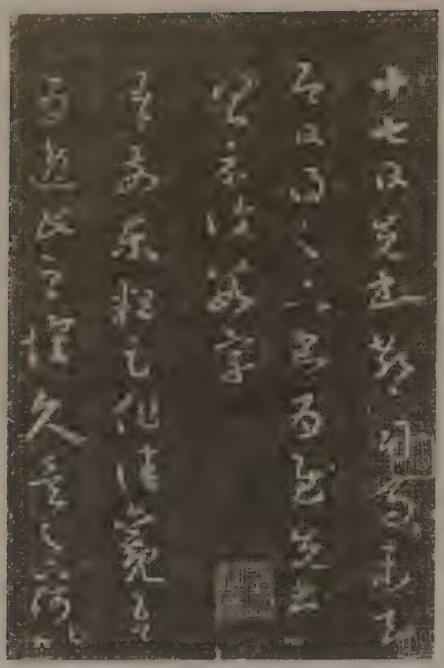
Beginning of aesthetic theory in China

In the Southern Liang dynasty critical works were written on literature and calligraphy; and, about the mid-6th century, the painter Hsieh Ho compiled the earliest work on art theory that has survived in China, the *Ku-hua p'in-lu* ("Classified Record of Painters of Former Times"). In this work he grades 27 painters in three classes, prefacing his list with a short statement of six aesthetic principles by which painting should be judged. These are: *ch'i yün sheng tung* ("spirit resonance, life-motion"), an enigmatic and much debated phrase that means that the painter should endow his work with life and movement through harmony with the spirit of nature; *ku fa yung pi* ("structural method in use of the brush"), referring to the structural power and tension of the brushstroke, alike in painting and calligraphy, through which the vital spirit is expressed; *ying wu hsiang hsing* ("fidelity to the object in portraying forms"); *sui lei fu ts'ai* (conforming to kind in applying colours); *ching ying wei chih* (planning and design in placing and positioning); and *ch'uan i mu hsieh* (transmission of ancient models by copying). Of the "six principles," the first two are fundamental, for, unless the conventional forms are brought to life by the vitality of the brushwork, the painting has no real merit, however carefully it is executed; the latter principles imply that truth to nature and tradition also must be obtained for the first two to be achieved. The six principles of Hsieh Ho have become the cornerstone of Chinese aesthetic theory down through the centuries.

The integration of spirituality and naturalism is similarly found in the short, profoundly Taoist text of the early 5th century, *Hua shan-shui hsü* ("Preface on Landscape Painting," China's first essay on the topic), attributed to Tsung Ping. Tsung suggests that if well-painted—that is, if both visually accurate and aesthetically compelling—a landscape painting can truly substitute for real nature, for, even though miniaturized, it can attract vital energy (*ch'i*) from the spirit-filled void (Tao), just as its real, material counterpart does. This interplay between macrocosm and microcosm became a constant foundation of Chinese spiritual thought and aesthetics.

Calligraphy. The fine art of writing, calligraphy, has often been held to occupy the highest place among the visual arts in China. The direct ancestor of modern writing, the script used on oracle shells and bones (*chia-ku-wen*) of the middle and late Shang dynasty, had already developed into a complex, semi-pictorial system. It gradually evolved into the large seal script (*ta-chuan shu*) seen in cast bronze inscriptions throughout the late Shang and the Chou dynasty. In the Ch'in dynasty unity was imposed by the government in the form of small seal script (*hsiao-chuan*). Perhaps because these early styles were often used for engraving inscriptions, they are all characterized by unmodulated brush lines and do not show to any advantage the expressive qualities permitted by the flexible Chinese brush. This latter quality first appeared in the Han dynasty in the form of clerical script (*li-shu*), perhaps aided by improvements in the writing brush itself. Clerical script is characterized by powerfully expanding brushstrokes, with

Script styles



"On the Seventeenth," cursive script by Wang Hsi-chih (*c.* 307–365), T'ang or Sung dynasty ink rubbing after an engraved copy of an Eastern Chin dynasty manuscript. Rubbing in the Kyōto National Museum, Japan. 25.1 × 16.4 cm.

Kyoto National Museum, photograph, Shimizu Kogeisha Co., Ltd

angular starts, turns, and stops; it can be boldly expressive whether written with the brush or carved in formal inscriptions on stone stelae. A convenient cursive version of clerical script, known as draft script (*ts'ao-shu*), also was developed, with a reduced number of strokes and considerable linkage between them. Gradually, by the end of the Han, clerical script, influenced by draft script, developed a more fluent structure and form of brushwork that has survived to this day as China's standard script (*k'ai-shu*, or *cheng-shu*). Developing parallel to the draft script was a semicursive, or "running," script (*hsing-shu*). By the early Six Dynasties period, the highly flexible standard and cursive scripts had come to be perceived as a profound artistic medium, capable of communicating fundamental personal qualities, and writing in draft script became something of a cult activity among the literati.

Among the early famous masters of calligraphy in the late Han to early Six Dynasties period were Chang Chih, Ts'ai Yung, Chung Yu, and Lu Chi. Wang Hsi-chih (*c.* 303–*c.* 361), a master of the *k'ai, hsing,* and *ts'ao* styles, especially favoured Chung Yu's fluid style but studied the past broadly and achieved the first great historical synthesis of styles. His sons Wang Hsien-chih and Wang Hui-chih inherited his talents (the whole family seems also to have been engaged in occult Taoism, in which their calligraphy was used for mystic trance-writing). For a while, Wang Hsien-chih's more suave manner of calligraphy surpassed his father's more spontaneous art in popularity. But the father was idolized by the second T'ang dynasty emperor, T'ai-tsung, who had his works copied at the 7th-century court for widespread distribution and took almost all the originals to the tomb with him, including Wang's *Lan-ting hsü* ("Orchid Pavilion Preface"), the most hallowed work of visual art in all East Asian history; and for over a millennium Wang Hsi-chih has been imitated by nearly every Asian schoolchild with a brush. Wang Hsi-chih and his followers founded a southern style of calligraphy that is elegant and graceful and that contrasted with the somewhat archaic style in the north at that time. The latter, known especially from stelae inscriptions, perpetuated the bold and angular power of Han clerical script and belatedly came to rival Wang Hsi-chih's influence in the hands of 8th-century T'ang masters such as Chang Hsü, who effected a second great historical synthesis.

Ceramics. The increase in population in the lower Yangtze valley was a great stimulus to the pottery industry in the Six Dynasties. Kilns in Chekiang (the old kingdom of Yüeh) were producing a stoneware with an olive brown or greenish glaze. Examples of Yüeh ware jars, ewers, pitchers, and other grave goods have been found in 3rd- and 4th-century tombs in the Nanking region. They were made chiefly at Shao-hsing, at Shang-lin Lake, and at Te-ch'ing, north of Hang-chou, which also produced a stoneware with a glossy black glaze. During the Six Dynasties potters freed themselves from the influence of bronze design and produced shapes more characteristic of pottery. Yüeh stoneware

While most of the Chekiang wares are plain or simply decorated, "northern celadon," produced in Hopeh and Honan in the 6th century, is exotic in style, reflecting the taste of Turkish rulers and other cultural contacts with western Asia. Heavy funerary jars are adorned with acanthus and lotus leaves, and flowers and round decorative plaques are molded or applied to the surface in imitation of Sāsānian repoussé metalwork. Tomb figurines of this period are often made of dark gray earthenware and unglazed, though sometimes they are painted.

Sui (581–618) and T'ang (618–907) dynasties. The founding of the Sui dynasty reunited China after more than 300 years of fragmentation. The second Sui emperor engaged in unsuccessful wars and vast public works, such as the Grand Canal linking the north and south, that exhausted the people and caused them to revolt. The succeeding T'ang dynasty built a more enduring state on the foundations the Sui rulers had laid, and the first 130 years of the T'ang was one of the most prosperous and brilliant periods in the history of Chinese civilization. The empire now extended so far across Central Asia that for a while Bukhara and Samarkand were under Chinese control, the Central Asian kingdoms paid China tribute, and Chinese cultural influence reached Korea and Japan. Ch'ang-an became the greatest city in the world; its streets were filled with foreigners, and foreign religions—including Zoroastrianism, Buddhism, Manichaeism, Nestorianism, Christianity, Judaism, and Islām—flourished. This confident cosmopolitanism is reflected in all the arts of this period.

The splendour of the dynasty reached its peak between 712 and 756 under Hsüan-tsung (or Ming-huang), but before the end of his reign a disastrous defeat lost Central

Asia to the advancing Arabs, and the rebellion of General An Lu-shan in 755 almost brought down the dynasty. Although the T'ang survived another 150 years, its great days were over; and, as the empire shrank and the economic crisis deepened, the government and people turned against foreigners and foreign religions. In 845 all foreign religions were briefly but disastrously proscribed; temples and monasteries were destroyed or turned to secular use, and Buddhist bronze images were melted down. Today the finest Buddhist art and architecture in the T'ang style is to be found not in China but in the 8th-century temples at Nara in Japan. While the ancient heartland of Chinese civilization in the Honan-Shensi area sank in political and economic importance, the southeast became ever more densely populated and prosperous, and in the last century of the T'ang it was once again the cultural centre of China, as it had been in the Six Dynasties.

Decline of the T'ang

Architecture. The Sui capital, Ta-hsing, was designed in 583 on Imperial order by the great architect Yü-wen K'ai; renamed Ch'ang-an, it was further developed by the T'ang after 618. This vast city, six times the size of present-day Sian, was laid out in nine months on a grid plan, with eastern and western markets and the Imperial City placed in the central northern section, a plan later followed at Peking. In 634 T'ang T'ai-tsung built a new palace, the Ta-ming Palace, on higher ground just outside the city to the northeast. The site of the Ta-ming Palace, which became the centre of court life during the glittering reigns of Kao-tsung (649–683) and Hsüan-tsung (712–756), has recently been partly excavated. Remains have been found of two great halls, Han-yüan Hall, with its elevated corridors extended like huge arms toward overlapping triple towers (foreshadowing the later Japanese Phoenix Hall at Uji and the Wu Gate at Peking), and the Lin-te Hall; marble flagstones and bases of 164 columns of the latter give some indication of its splendour. Lost marvels of Sui-T'ang palace architecture include Yü-wen K'ai's rotating pavilion in the Sui palace, which could hold 200 guests, and the 90-metre-high state Ming-t'ang ("Spirit Hall") built for China's only reigning empress, the usurper Wu-hou (or Wu Tse-t'ien, who changed the name of the dynasty from T'ang to Chou during her reign from 690 to 705). Surviving murals from Buddhist caves at Tun-huang and excavated royal tombs near Ch'ang-an provide a graphic record of T'ang architecture, its taste for multistory elevation, tall towers, and elaborate elevated walkways, its somewhat garish use of coloured-tile building surfaces, and its integration of architecture with gardens, ponds, and bridges.

The Sui-T'ang period saw some of China's most lavish royal tomb building, before the onset of a relative modesty in the Sung and a decline of qualitative standards in later periods. Excavated royal tombs at Ch'ang-ling, north of the capital, include three built for close relatives of Wu-hou who were degraded or executed by her on her way to the throne and reburied amid much pomp and splendour in 706 after the restoration of the T'ang royal lineage. In each, the subterranean sepulchre is surmounted by a truncated pyramidal tumulus and is approached through a sculpture-lined "spirit way" (*ling-tao*). Inside, painted corridors and incised stone sarcophagi provide a lingering record of T'ang splendour, with colourful renderings of palatial settings, foreign diplomats, servants-in-waiting, and recreation at polo and the hunt. Along the corridor, niches that had served temporarily as ventilating shafts are stuffed with ceramic figurines, riders and entertainers, T'ang horses and other fabulous animals, mostly done in bold tricolour glazes. The corridor leads to two domed vaults serving as an antechamber and burial hall. The tombs of some T'ang rulers were so grand that artificial tomb mounds no longer sufficed, and funerary caverns were carved out beneath large mountains. The huge tomb of Emperor Kao-tsung and his empress, Wu-hou (China's only joint burial of rulers), at Ch'ang-ling, has yet to be excavated but appears to be intact.

The Sui and the first half of T'ang were great periods of temple building. The first Sui emperor distributed relics throughout the country and ordered that pagodas and temples be built to house them, and the early T'ang monarchs were equally lavish in their foundations. Apart from masonry pagodas, however, very few T'ang temple buildings have survived. The oldest yet identified is the main hall of Nan-ch'an Temple at Wu-t'ai in northern Shansi (before 782); the largest is the main hall of nearby Fo-kuang Temple (857). The Great Buddha Hall (Daibutsu-den, 752) of the Tōdai Temple (Todai-ji) at Nara in Japan, 88 metres long and 51.5 metres wide, built in the T'ang style, is today the largest wooden building in the world; however, it is small compared with the lost T'ang temple halls of Lo-yang and Ch'ang-an.

T'ang and later pagodas show little of the Indian influence that was so marked on the Sung-yüeh Temple pagoda. T'ang wooden pagodas have all been destroyed, but graceful examples survive at Nara, notably at Hōryū Temple, Yakushi Temple, and Daigō Temple. Masonry pagodas include the seven-story, 58-metre-high Ta Yen T'a, or Great Wild Goose Pagoda, of Tz'u-en Temple in Ch'ang-an, on which the successive stories are marked by corbeled cornices, and timber features are simulated in stone by flat columns, or pilasters, struts, and capitals.

Masonry pagodas

T'ang cave-temples at Tun-huang were increasingly Sinicized, abandoning the Indianesque central pillar, the circumambulated focus of worship which in Six Dynasties caves was sculpted and painted on all four sides with Buddhist paradises; in the T'ang, major Buddhist icons and paradise murals were moved to the rear of an open chamber and given elevated seating, much like an emperor enthroned in his palace or like any Chinese host.

Sculpture. Although the Sui emperors were great patrons of Buddhism, there were no major changes in style during this brief period. T'ang T'ai-tsung was hostile to Buddhism, but his successor, Kao-tsung, and Empress Wu were lavish in their endowments. Under Kao-tsung, the principal cave shrine, Feng-hsien Temple, was carved out at Lung-men between 672 and 675. The central figure, cut almost in the round, is the cosmic Buddha Vairocana (one of the Five Celestial Buddhas), whose worship had recently been introduced with the doctrines of the Esoteric Chen-yen sect. The figure, 11 metres high, is compact, restrained, and somewhat severe in conception; the head and body are massively yet delicately modeled, and the features and drapery are sharply carved, as though painted with a fine brush.

The next 50 years saw the climax of the fourth phase of Chinese Buddhist sculpture, in which Indian mass and Chinese rhythmic line were triumphantly united and rec-

onciled. The high point came about 690–710, in the early caves at T'ien-lung Shan, carved under the patronage of Empress Wu. The largest and finest bronze pieces in this style are a bronze Yakushi flanked by bodhisattvas (Yakushi Temple, Nara); no examples of comparable quality have survived in China.

"Baroque" style of sculpture

The mature style of the 8th century is well displayed in later caves at T'ien-lung Shan, carved for the emperor Hsüan-tsung. Here the modeling is much fuller and more fleshy, the poses more exaggerated, and the drapery sweeps over the partly exposed body in an emphatic manner very different from the restrained nobility of the 7th century. (This "baroque" style was an expression not only of Indian sculptural influences but also of the confident materialism of high T'ang culture, when the spiritual message of Buddhism seemed less important than the lavish endowment of temples and images and the display of religious extravagance that was one of the chief causes of the anti-Buddhist campaign of 845.

Painting. The patronage of the Sui and T'ang courts attracted painters from all over the empire. Yen Li-pen, who rose to high office as an administrator, finally becoming a minister of state, was also a noted 7th-century figure painter. His duties included painting historical scrolls, notable events past and present, and portraits, including those of foreigners and strange creatures brought to court as tribute, to the delight of his patron, T'ai-tsung. Yen Li-pen painted in a conservative style with a delicate, scarcely modulated line. Part of a scroll depicting 13 emperors from Han to Sui (in the Museum of Fine Arts, Boston) is attributed to him.

The royal tombs near Sian (706) show the emergence of a more liberated tradition in brushwork that came to the fore in mid- to late-8th-century painting, as it did in the calligraphy of Chang Hsü, Yen Chen-ch'ing, and other master writers. The greatest brush master of T'ang painting was the 8th-century artist Wu Tao-hsüan, who was also called Wu Tao-tzu and who not only enjoyed a career at court but had sufficient creative energy to execute, according to T'ang records, some 300 wall paintings in the temples of Lo-yang and Ch'ang-an. His brushwork, in contrast to that of Yen Li-pen, was full of such sweeping power that crowds would gather to watch him as he worked. He painted chiefly in ink, leaving the colouring to his assistants, and was famous for the three-dimensional, sculptural effect he achieved with the ink line alone. Only descriptions of his work (*e.g.*, a mural at the Ta-t'ung Hall of the Imperial palace, representing almost 500 kilometres of Szechwan's Chia-ling River, produced in a single day without preliminary sketches) and very unreliable copies survive. Wu Tao-tzu had a profound influence, particularly on figure painting, in the T'ang and Sung dynasties.

Influence of Wu Tao-tzu

Figure painters who depicted court life in a careful manner derived from Yen Li-pen rather than from Wu Tao-tzu included Chang Hsüan and Chou Fang. Eighth-century royal tomb murals and Tun-huang Buddhist paintings demonstrate the early appearance and widespread appeal of styles that these court artists helped later to canonize, with individual figures (especially women) of monumental, sculpturesque proportion arranged upon a blank background with classic simplicity and balance.

Horses played an important role in T'ang military expansion and in the life of the court; riding was a popular recreation, and even the court ladies played polo. Horses also had become a popular subject for painting, and one of the emperor Hsüan-tsung's favourite court artists was the horse painter Han Kan. The other great horse painting master was the army general Ts'ao Pa, said by the poet Tu Fu to have captured better the inner character of his subjects and not just the flesh. Most later horse painters claimed to follow Han Kan or Ts'ao Pa, but the actual stylistic contrast between them was already reported in Northern Sung times as no longer distinguishable and today is hardly understood.

"Blue-and-green" style of landscape painting

The more than three centuries of the Sui and T'ang were a period of progress and change in landscape painting. The early 7th- and 8th-century masters Chan Tzu-ch'ien, Li Ssu-hsün, and the latter's son Li Chao-tao developed a style of landscape painting known as *ch'ing-lü-pai* ("green, blue, white"), or *chin-pi shan-shui* ("gold-blue-green"), in which mineral colours were applied to a composition carefully executed in fine line to produce a richly coloured effect. Probably related to Central Asian painting styles of the Six Dynasties period and associated with the jeweled-paradise landscapes of the Taoist immortals, this "blue-and-green" type readily appealed to the T'ang court's taste for international exotica, religious fantasy, and boldly decorative art. A painting in this technique, known as "Ming-huang's Journey to Shu" (that is, Szechwan; in the National Palace Museum, Taipei), reflects what is considered to be the style of Li Chao-tao, although it is probably a later copy. This style gradually crystallized as a courtly and professional tradition, in contrast to the more informal calligraphic ink painting of the literati.

The traditional founder of the school of scholarly landscape painting (*wen-jen hua*) is Wang Wei, an 8th-century scholar and poet who divided his time between the court at Ch'ang-an, where he held official posts, and his country estate of Wang Ch'uan, of which he painted a panoramic composition preserved in later copies and engraved on stone. Among his Buddhist paintings, the most famous

was a rendering of the Indian sage Vimalakīrti, who became, as it were, the "patron saint" of Chinese Buddhist intellectuals. Wang Wei sometimes painted landscapes in colour, but his later reputation was based on the belief that he was the first to paint landscape in monochrome ink. He was said to have obtained a subtle atmosphere by "breaking the ink" (*p'o-mo*) into varied tones. The belief in his founding role, fostered by later critics, became the cornerstone of the philosophy of the *wen-jen hua*, which held that a man could not be a great painter unless he was also a scholar and a gentleman.

More adventurous in technique was the somewhat eccentric late-8th-century painter Chang Tsao, who produced dramatic tonal and textural contrasts, as when he painted simultaneously, with one brush in each hand, two branches of a tree, one moist and flourishing, the other desiccated and dead. This new freedom with the brush was carried to extremes by such painters of the middle to late T'ang as Wang Hsia (or Wang Mo) and Ku K'uang, southern Chinese Taoists who "splashed ink" (also transliterated as *p'o-mo* but written with different characters than "broken ink") onto the silk in a manner suggestive of 20th-century Action painters. The intention of these ink-splashers was philosophical and religious as well as artistic: it was written at the time that their spontaneous process was designed to imitate the divine process of creation. Their semi-finished products, in which the artistic process was fully revealed and the subject matter had to be discerned by the viewer, suggested a Taoist philosophical skepticism. These techniques marked the emergence of a trend toward eccentricity in brushwork that had free rein in periods of political and social chaos. They were subsequently employed by painters of the southern "sudden" school of Ch'an (Zen) Buddhism, which held that enlightenment was a spontaneous, irrational experience that could be suggested in painting only by a comparable spontaneity in the brushwork. Ch'an painting flourished particularly in Ch'eng-tu, the capital of the petty state of Shu, to which many artists went as refugees from the chaotic north in the last years before the T'ang dynasty fell, among them the eccentric artists Kuan-hsiu and Shih K'o.

Trend toward eccentricity in brushwork

Calligraphy. As T'ang painting moved in the direction of greater linear expressiveness, it came increasingly under the sway of developments in calligraphy, not only in technique and style but in aesthetic theory as well. The Sinicization of the Turkic rulers of the Northern Wei by the late 5th century and the reunification of China under the Sui and T'ang a century later paved the way for an infusion of southern taste at the court in the north and, gradually, for a synthesis of southern and northern styles. The passionate accumulation and distribution through careful copywork of Wang Hsi-chih's surviving manuscripts by the second T'ang dynasty emperor, T'ai-tsung, represents this infusion and was accompanied by widespread calligraphic activity at the court, where Ou-yang Hsün, Yü Shih-nan (a pupil of Wang Hsi-chih's 7th-generation descendant, the priest Chih-yung), and Ch'u Sui-liang were among the many brush masters of lasting fame who were gathered to serve as copyists for the emperor and the nation. T'ai-tsung himself was a notable writer, as was his descendant of the next century, Hsüan-tsung.

It was during Hsüan-tsung's reign that Chinese calligraphy reached a third definitive period, comparable to the Ch'in unification of seal script and the Wang family's synthesis of earlier styles. The three greatest masters involved in synthesizing southern and northern tendencies, blending fluid brush movement and expressive power, were Chang Hsü (known for his "delirious cursive" writing) and his pupils Yen Chen-ch'ing and the monk Huai-su (the latter practicing a "wild cursive"—*k'uang-ts'ao*—style). They helped establish a new aesthetic standard that would soon pervade painting as well as calligraphy, more fully than ever before realizing in visual form the ancient aesthetic principles of "natural" emotionality and "sincerity" in rendering. Their preference for rugged, intentionally awkward, or altogether surprising forms was quite different from the elegant polish of the earlier, southern Chinese styles; and their emphasis on expressing character and emotion was handed down through Liu Kung-ch'üan of the next century and enshrined as the dominant manner of the Sung dynasty by Su Shih, Huang T'ing-chien, and Mi Fu of the 11th century.

T'ang masters of calligraphy

Ceramics. After the comparative sterility of the Six Dynasties, this was a great period in the development of Chinese pottery. Although a white porcelain perfected early in the 7th century is called Hsing *yao* (Hsing "ware") because of a reference to white porcelain of Hsing-chou in the 9th-century essay *Ch'a Ching* ("Tea Classic") by Lu Yü, as yet no kilns have been found there. Kilns near Ting-chou in Hopeh, however, were at this time already producing a fine white porcelain, ancestor of the famous Ting ware of the Northern Sung. Late-7th- and 8th-century ceramists in northern China, working primarily at kilns at T'ung-ch'uan near Ch'ang-an and at Kung-hsien in Honan province, also developed "three-colour" (*san ts'ai*) pottery wares and figurines that were slipped and covered with a low-fired lead glaze tinted with copper or ferrous oxide in green, yellow, brown, and sometimes blue; the bright colours were allowed to mix or run naturally over the robust contour of these vessels, which are among the finest in the history of Chinese pottery. Northern Chinese kilns in Shensi also produced a stoneware with a rich black glaze, and a type of celadon was made north of Sian, in Shensi. The northern Chinese potters borrowed shapes and motifs from western Asia even more freely than had their 6th-century predecessors; foreign shapes include the amphora, bird-headed ewer, and rhyton; foreign motifs include hunting reliefs, floral medallions, boys with garlands or swags of vines, and Buddhist symbols adapted and applied with characteristic T'ang confidence. Some forms were borrowed from metalwork or glassware.

Tomb figurines were produced in such enormous quantities that attempts were made through sumptuary laws to limit their number and size, but they met with little success. The figurines were made, generally in molds, of earthenware covered with slip and painted or glazed or both. Among the human figures are servants and actors, female dancers, and musicians of exquisite grace. The 7th-century figurines are slender and high-waisted, those of the 8th century are increasingly rotund and round-faced, reflecting a change in fashion. There are also many figurines of Central Asian grooms and Semitic merchants, whose deep-set eyes and jutting noses are caricatured. Of the camels and horses, the most remarkable are glazed camels bearing on their backs a group of four or five singers and musicians. After the middle of the 8th century, there was a sharp decline both in the quantity and in the quality of northern China tomb wares and figurines.

The great southward movement of population in the T'ang dynasty stimulated the development of many new kilns. Celadons were now made in Chiung-lai (Szechwan), Ch'ang-sha (Hunan), and several areas of Kwangtung and Fukien. A kiln producing whitewares was active at Chi-chou in Kiangsi, and at Ching-te-chen in the same province two kilns were producing celadons and whitewares. From these humble beginnings, Ching-te-chen was destined to become, in the Ming and Ch'ing dynasties, the largest pottery factory in the world. In the *Ch'a Ching*, the celadons of Yüeh-chou in Chekiang are ranked for their jadelike quality first among the wares suitable

Yüeh celadons

for tea drinking, followed by the silvery Hsing ware.

Metalwork. The metalwork and jewelry of the T'ang period are witness to the wealth and cosmopolitanism of T'ang culture. Silver and silver-gilt ritual objects of many kinds have been found in T'ang tombs, including vases, ewers, dishes, bowls, wine cups, and incense burners. While some shapes are traditional Chinese, others are foreign. Alms bowls, *kuṇḍikā* water bottles (Buddhist ewers used in the initiation of monks), and reliquaries arrived with Buddhism from India; a polylobed cup, platter with relief decoration, ewer, and handled cup are of Sāsānian origin; the rhyton drinking cup is ultimately Greek. Among decorative motifs, the pearl band, cloud volute, curl border, dragons, and phoenixes are Chinese; hunting scenes, vine scrolls, rosettes, and opposed birds or animals in roundels are Sāsānian; and from India came Buddhist themes, lotus scrolls, and much of the floral ornament.

Sui and T'ang bronze mirrors

Many of the finest Sui and T'ang bronze mirrors were made at Yang-chou on the Grand Canal. Decoration, cast in high relief or repoussé, includes auspicious motifs, Taoist scenes, and the 12 zodiacal animals. The "lion and grape" mirror was very popular in the 7th and 8th centuries, for it embodied both Chinese directional and "Five Phases" symbolism, and lions and grapes were also potent symbols in the Manichaean faith introduced by the Uighur from Central Asia. This type of mirror disappeared abruptly with the persecution of the Manichaeans in 843.

Decorative arts: collection in the Shōsō-in treasure house. The Shōsō-in treasure house, a timber structure in Nara, Japan, was built to receive the personal treasures bequeathed to the Tōdai Temple by the emperor Shōmu, who died in 756. While subsequent deposits gradually added to the collection, the original gift embraced more than 600 items, which included Buddhist ritual objects, furniture, musical instruments, textiles, metalwork, lacquerwork, cloisonné, glassware, pottery, painted screens, calligraphy, and maps. Many of these pieces must have been made in Japan, but they are for the most part typically T'ang in style and decoration. This collection of T'ang-style decorative arts and crafts is the greatest in the world. Its importance lies in the fact that it is exactly datable to 756 or earlier, nearly all the pieces are in excellent condition, and they include types of decoration and technique of which no examples have survived in China.

Five Dynasties (907–960) and Ten Kingdoms (902–978). At the fall of the T'ang, northern China, ruled by five short-lived dynasties, plunged into a state of political and social chaos. The corrupt northern courts offered little support to the arts, although Buddhism continued to flourish until persecution in 955 destroyed much of what had been created in the 110 years since the previous anti-Buddhist campaign. The 10 independent kingdoms that ruled various parts of southern China, though no more enduring, offered more enlightened patronage. At first, the Ch'ien (Former) Shu (with its capital at Ch'eng-tu), then, for a longer period, the kingdoms of the Nan (Southern) T'ang (with the capital at Nanking) and Wu-Yüeh (with its capital at Hang-chou) were centres of comparative peace and prosperity. Li Hou-chu (or Li Yü), the last ruler of the Southern T'ang, was a poet and liberal patron at whose court the arts flourished more brilliantly than at any time since the mid-8th century. Not only were the southern courts at Ch'eng-tu and Nanking leading patrons of the arts but they also began formalizing court sponsorship of painting by organizing a centralized atelier with an academic component and by granting painters an elevated bureaucratic stature—policies that would be followed or modified by subsequent dynasties.

The greatest of the northern painters

Painting. In northern China only a handful of painters were working. The greatest of them, Ching Hao, who was active from about 910 to 950, spent much of his life as a recluse in the T'ai-hang Mountains of Shansi. No authentic work of his survives, but he seems from texts and later copies to have created a new style of landscape painting. Boldly conceived and executed chiefly in ink with firmness and concentration, his precipitous crags, cleft with gullies and rushing streams, rise up in rank upon rank to the top of the picture. For 150 years before his time the centre of landscape painting had been in the southeast, and Ching Hao's importance lies in the fact that he both revived the northern spirit and created a type of painting that became the model for his follower Kuan T'ung and the classic northern masters of the early Sung period, Li Ch'eng and Fan K'uan. An essay on landscape painting, "Pi-fa chi" ("Notes on Brushwork"), attributed to Ching Hao, sets out the philosophy of this school of landscape painting, one that was consistent with newly emergent Neo-Confucian ideals. Painting was to be judged both by its visual truthfulness to nature and by its expressive impact. Consistent with this, in all the major schools of Sung landscape painting that followed, artists would render with remarkable accuracy their own regional geography, letting it serve as a basis for their styles, their emotional moods, and their personal visions.

In contrast to the stark drama of this northern style, landscapes associated with the name of Tung Yüan, who held a sinecure post at the court of Li Hou-chu in Nanking, are broad, almost Impressionist in treatment. The coarse brushstrokes (known as "hemp-fibre" texture strokes), dotted accents ("moss dots"), and wet ink washes of his monochrome style, said to be derived from Wang Wei, suggest the rounded, tree-clad hills and moist atmosphere of the Chiang-nan ("South of the River") region. The contrast between the firm brushwork and dramatic compositions of such northern painters as Ching Hao and his followers and the more relaxed and spontaneous manner of Tung Yüan and his follower Chü-jan laid the foundation for two distinct traditions in Chinese landscape painting that have continued up to modern times. The style developed by Tung Yüan and Chü-jan became dominant in the Ming and Ch'ing periods, preferred by amateur artists because of its easy reduction to a calligraphic mode, its calm and understated compositional nature, and its regional affiliation.

While the few figure painters in northern China, such as Hu Huai, characteristically recorded hunting scenes, the southerners, notably Ku Hung-chung and Chou Wen-chü, depicted the voluptuous, sensual court life under Li Hou-chu. A remarkable copy of an original work by Ku Hung-chung depicts the scandalous revelries of the minister Han Hsi-tsai. Chou Wen-chü was famous for his pictures of court ladies and musical entertainments, executed with a fine line and soft, glowing colour in the tradition of Chang Hsüan and Chou Fang.

Flower painting

Flower painting, previously associated chiefly with Buddhist art, came into its own as a separate branch of painting in the Five Dynasties. At Ch'eng-tu, the master Huang Ch'üan brought to maturity the technique of *mo-ku hua* ("boneless painting"), in which he applied light colours with delicate skill, hiding the intentionally pale underdrawing and seeming thereby to dispense with the usually dominant element of strong brush outline. His great rival, Hsü Hsi, working for Li Hou-chu in Nanking, first drew his flowers in ink in a bold, free manner suggestive of the draft script, *ts'ao-shu,* adding a little colour afterward. Both men established standards that were followed for centuries afterward. Because of its reliance on technical skill, Huang Ch'üan's naturalistic style (also referred to as *hsieh-sheng,* or "lifelike painting"), was mainly adopted by professional painters, while the scholars admired the calligraphic freedom of Hsü Hsi's style (referred to as *hsieh-i,* or "painting the idea"). After the founding of the Sung, *hsieh-sheng* artists from Szechwan, including Huang Ch'üan and his sons Huang Chü-ts'ai and Huang Chü-pao, traveled to the new court at Pien-ching (K'ai-feng), where they established a tradition that dominated the Northern Sung period. Hsü Hsi found greater favour in the Yüan, Ming, and Ch'ing periods.

Ceramics. The confusion of northern China under the Five Dynasties was not conducive to development of the pottery industry, and some types such as the T'ang three-colour wares went out of production completely. White porcelain and black glazed stonewares, however, continued into the Sung dynasty. By contrast, the flourishing southern courts and the massive increase in the population of southeastern China were a great stimulus to the craft. A large complex of kilns that had been established at Yü-yao, around the Shang-lin Lake in Chekiang, which

lay in the territory of the kingdom of Wu-Yüeh, sent its finest celadons to the court of Li Hou-chu until his realm fell to the Sung in 978; after that they were sent as tribute to the Sung court at Pien-ching. The finest pieces, with decoration carved in the clay body under a very pale olive green glaze, were called by 10th-century writers, who implied that the colour was produced in imitation of jade, *pi-se yao* ("secret," or "reserve, colour ware"). It is not known whether this referred to a secret process or to the fact that the ware was reserved for the court.

Sung (960–1279), Liao (907–1125), and Chin (1115–1234) dynasties. Although reunited and ably ruled for well over a century by the first five Sung emperors, China failed to recover the northern provinces from the barbarians. A Khitan tribe, calling their dynasty Liao, held all of northeastern China until 1125, while the Hsi (Western) Hsia held the northwest, cutting off Chinese contact with western and Central Asia. From the new capital, Pien-ching, the Sung rulers pursued a pacific policy, buying off the Khitan and showing unprecedented toleration at home. While it brought Chinese scholarship, arts, and letters to a new peak of achievement, this policy left the northern frontiers unguarded. When in 1114 the Juchen Tatars in the far northwest revolted against the Khitan, the Chinese army helped the rebels destroy their old enemy. The Juchen then turned on the Sung, invaded China, beseiged the capital in 1126, and took the emperor Ch'in-tsung, the emperor emeritus Hui-tsung, who had recently abdicated, and the Imperial court prisoner, establishing their own dynasty, the Chin, with their capital at the city later to be called Peking. The remnants of the Sung court fled to the south in 1127 and, after several years of wandering, established their "temporary" capital at the beautiful city of Hang-chou. The Nan (Southern) Sung never seriously tried to recover the north but enjoyed the beauty and prosperity of their new home, while the arts continued to flourish in an atmosphere of humanity and tolerance until the Mongols entered China in the 13th century and swept all before them. In 1234 they destroyed the Juchen Tatars, and, although the Chinese armies resisted valiantly, Hang-chou fell in 1276. Three years later a loyal Sung minister drowned himself and the young emperor.

Fall of the Northern Sung

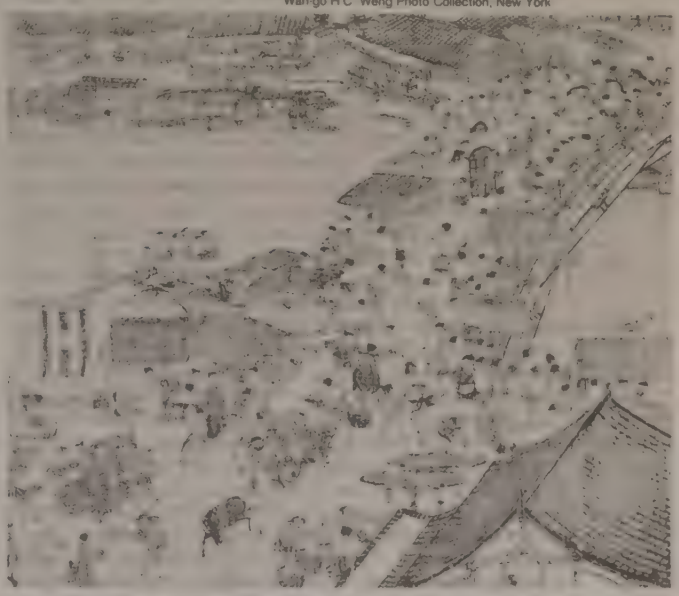
The Pei (Northern) Sung was a period of reconstruction and consolidation. Pien-ching was a city of palaces, temples, and tall pagodas; Buddhism flourished, and monasteries and temples once again multiplied. The Sung emperors attracted around them the greatest literary and artistic talent of the empire, and something of this high culture was carried on by their successors of Liao and Chin. The atmosphere at the Southern Sung court in Hang-chou, while if possible more refined and civilized, was clouded by the loss of the north; the temptation to enjoy the delights of Hang-chou and neglect their armies on the frontier turned men in on themselves. The power and confidence are gone from Southern Sung art; instead it is imbued with an exquisite sensibility, a sometimes poignant romanticism that seems for all its beauty to contain the seeds of the disaster that befell China in the 13th century.

Sung interest in history and a revival of the Classics were matched by a new concern with the tangible remains of China's past. This was the age of the beginning of archaeology and of the first great collectors and connoisseurs. One of the most enthusiastic of these was the Northern Sung emperor Hui-tsung (1100–1125/26), whose passion for the arts blinded him to the perils that threatened his country. Hui-tsung's sophisticated antiquarianism reflects an attitude that became an increasingly important factor in Chinese art. He collected and cataloged pre-Ch'in bronzes and jades while the palace studios turned out close replicas and archaistic emulations of both media. Building his royal garden, the Ken-yüeh, was said to have nearly bankrupted the state, as gigantic garden stones hauled up by boat from the south closed down the Grand Canal for long periods. He was also the most distinguished of all Imperial painting collectors, and the catalog of his collection (the *Hsüan-ho hua-p'u*, encompassing 6,396 paintings by 231 painters) remains a valuable document for the study of early Chinese painting. (Part of the collection passed into the hands of the Chin conquerors, and the remainder was scattered at the fall of Pien-ching.) Hui-tsung also elevated to new heights the recent process of bureaucratizing court painting, with entrance examinations modeled on civil service norms, with ranks and promotions like those of scholar-officials, and with regularized instruction sometimes offered by the emperor himself as chief academician. The favours granted throughout the Sung to lower-class artisans at court incurred the ire of aristocratic courtiers and provided stimulus for the rise of the amateur painting movement among these scholar-officials (*shih-ta-fu hua*), which ultimately became the literati painting mode (*wen-jen hua*) that dominated most of Yüan, Ming, and Ch'ing history.

Bureaucratization of court painting

Architecture. The Sung capital, Pien-ching, grew to a great city, only to be burned by Juchen Tatars in 1127, just after the work was completed. Nothing survives today, but some idea of the architecture of the city is given by a remarkably realistic hand scroll, "Going Up the River at Ch'ing-ming Festival Time," painted by the 12th-century court artist Chang Tse-tuan (whether painted before or after the sacking is uncertain). From contemporary accounts, Pien-ching was a city of towers, the tallest being a pagoda 110 metres high, built in 989 by the architect Yü Hao to house a relic of the Indian emperor Aśoka. Palaces and temples were at first designed in the T'ang tradition, sturdy and relatively simple in detail though smaller in scale. The plan and grouping of the elements, however, became progressively more complex; temple halls were often built in two or three stories, and structural detail became more elaborate.

Wan-go H C Weng Photo Collection, New York



"Going Up the River at Ch'ing-ming Festival Time," detail of a hand scroll by Chang Tse-tuan (12th century), Sung dynasty. Ink and colour on silk. In the Palace Museum, Peking. 24.8 cm × 528 cm.

The style of the 10th century is exemplified in the Kuan-yin Hall of the Tu-le Temple at Chi-hsien, Hopeh province, built in 984 in Liao territory. A two-story structure with a mezzanine that projects to an outer balcony, the hall is effectively constructed of three tiers of supporting brackets. It houses a 16-metre-high 11-headed clay sculpture of Kuan-yin, the largest of its kind in China, placed majestically beneath a central canopy. From the 11th century, the finest surviving buildings are the main hall and library of the Hua-yen Temple in the Liao capital at Ta-t'ung (Shansi), which was accorded the right to house images of the Liao emperors, installed in 1062. The library, perhaps the most intricate and perfectly preserved example of the architecture of the period, was completed in 1038.

The new Sung style is characterized by a number of distinct features. The line of the eaves, which in T'ang architecture of northern China was still straight, now curves up at the corners, and the roof has a pronounced sag-

ging silhouette. The bracket cluster (*tou-kung*) has become more complex: not only is it continuous between the columns, often including doubled, or even false, cantilever arms (or "tail-rafters," *hsia-ang*), which slant down from the inner superstructure to the bracket, but also a great variety of bracket types may be used in the same building (56 different types are found in the five-story wooden pagoda built in 1056 at the Fo-kung Temple in Ying-hsien, Shansi province). The tail-rafter, hitherto anchored at the inner end to a crossbeam, now is freely balanced on the bracket cluster, supporting purlins (horizontal timbers) at each end, thus giving the whole system something of the dynamic functionalism of High Gothic architecture. The interior is also much more elaborate. Richly detailed rounded vaults, or cupolas, are set in the ceiling over the principal images.

Practically nothing survives today of the Southern Sung capital of Hang-chou, described as the greatest city in the world by the Venetian traveler Marco Polo, who spent much of the time from 1276 to 1292 in the city. The dense population and confined space of Hang-chou forced buildings upward, and many dwellings were in three to five stories. While palace buildings in the southern part of the city were probably crowded together, temples and high-platformed viewing pavilions overlooking West Lake were buildings of fairylike beauty. They survive today only in the work of such Southern Sung landscape and architecture painters as Li Sung.

Variety of form, structural technique, detail, and decoration of Sung architecture reflect the sophistication of Sung culture and a new intellectual interest in the art. Master builders such as Yü Hao and the state architect Li Chieh were educated men. The latter is known today chiefly as the compiler of *Ying-tsao fa-shih* ("Building Standards"), which he presented to the throne in 1100. This illustrated work deals in encyclopaedic fashion with all branches of architecture: layout, construction, stonework, carpentry, bracketing, decoration, materials, and labour. The *Ying-tsao fa-shih* became a standard text, and, while it was influential in spreading the most advanced techniques of the time of its first publication in 1103, by codifying practice it may also have inhibited further development and contributed to the conservatism of later techniques.

In contrast with the greater uniformity of later periods, Sung architecture was experimental and increasingly diverse in nature. Two styles from the Southern Sung period can be inferred from early Japanese buildings. One style is called by the Japanese *Tenjiku-yo,* or "Indian style," but it actually originated on the southeastern Chinese coast, where tall stands of evergreens stood. It sometimes employed timber columns rising to about 20 metres, directly into which were inserted vertical tiers of up to 10 transverse bracket-arms. This stern and simple style is exemplified by the Great South Gate at Tōdai Temple, built in Nara, Japan, about 1180. Another style, dubbed *Kara-yo* ("T'ang"—*i.e.,* Chinese—style), was brought by Ch'an (Zen) Buddhist priests from the Hang-chou area and south to the new shogunal capital at Kamakura, where it can be seen in the 13th-century Reliquary Hall of Engaku Temple. It features unpainted wood siding with multilevel paneled walls (no plaster wall or lacquered columns) and much attention to elaborative detail. The effect is rich and dynamic and displays none of the simplicity one might expect of Ch'an architecture, so it is thought by some to represent more a Chinese regional style than anything specifically Ch'an.

Sculpture. The tradition of Buddhist image making continued through the Sung, Liao, and Chin dynasties with slowly diminishing force. The sculpture of southern Chinese temples in and around Hang-chou has been destroyed, but much survives in the north. A typical example is the lower temple of Hua-yen Temple at Ta-t'ung (1038), with its three central seated Buddha figures, 5 metres high, of lacquered clay, and its sensuous, exquisitely mannered bodhisattvas. A realistic strain in Sung, Liao, and Chin sculpture shares with Ch'an painting of the late Sung and Yüan dynasties the power to suggest spiritual concentration through the strongly marked features of the image. A similar realism was attained in lohan figures

Painted clay bodhisattva, 11th century, Liao dynasty. In the lower Hua-yen Temple, Ta-t'ung, Shansi province.
Gao Lishuang/ChinaStock Photo Library

modeled in dry lacquer, a technique that was first used in China in the second half of the 6th century and of which the best surviving examples are to be found today at Nara in Japan. This realistic style of sculpture can also be seen at such sites as the Lung-men caves at Lo-yang, the Chin Tz'u at T'ai-yüan, and Ta-tsu in Szechwan.

Most majestic among Sung sculptures are images of Kuan-yin seated in a relaxed pose known as "royal ease." The body is sensuously modeled and the face full and slightly smiling; rich jewelry, scarves, and ribbons move over the surface, creating a dramatic play of light and shade that, like Baroque sculpture in Europe, was no doubt designed to win back adherents to the faith by its visual and emotional appeal. After the climax reached in this spectacular, somewhat florid style, there were no major developments in Chinese Buddhist sculpture, which preserved the essentials of this style, though with increasing coarseness, through the Yüan, Ming, and Ch'ing dynasties.

Painting and calligraphy. Settled conditions and a tolerant atmosphere helped to make the Northern Sung a period of great achievement in landscape painting. Li Ch'eng, a follower of Ching Hao who lived a few years into the Sung, was a scholar who defined the soft, billowing earthen formations of the northeastern Chinese terrain with "cloudlike" texture, interior layers of graded ink wash bounded by firmly brushed, scallop-edged contours. He is remembered especially for winter landscapes and for simple compositions in which he set a pair of tall, rugged, aging evergreens against a low, level view of desiccated landscape. As with Ching Hao and Kuan T'ung, probably none of his original work survives, but aspects of his style have been perpetuated in thousands of other artists' works. An even more formidable figure was the early

The painter Fan K'uan

11th-century painter Fan K'uan, who began by following Li Ch'eng's style, but turned to studying nature directly, and finally followed only his own inclinations. He lived as a recluse in the mountains of Shensi, and a Sung writer said that "his manners and appearance were stern and old-fashioned; he had a great love of wine and was devoted to the Tao." A tall landscape scroll, "Travelers Among Mountains and Streams" (National Palace Museum, Taipei), bearing his hidden signature, depicts peasants and pack mules emerging from thick woodland at the foot of a towering cliff that dwarfs them to insignificance. The composition is monumental, the detail is realistic, and the brushwork, featuring a stippling style known as "raindrop" strokes, is powerful and close-textured. While the details of the work are based on closely observed geographic reality (perhaps some specific site such as Mount Heng), a profoundly idealistic conception is revealed in the highly rational structure of the painting, which conforms closely to aspects of Taoist cosmology and numerology.

Other northern masters of the 11th century who helped to establish the great classical tradition were Hsü Tao-ning, Kao K'o-kung, and Yen Wen-kuei. The second half of the century was dominated by Kuo Hsi, who became an instructor in the painting division of the Imperial Hanlin Academy. His style combined the technique of Li Ch'eng with the monumentality of Fan K'uan; but it shows some advance, particularly in the effect of relief that he attained by shading with ink washes ("cloudlike" texture), a spectacular example of which is his "Early Spring" of 1072 (National Palace Museum, Taipei). He was a great decorator and liked to work on such large surfaces as plaster walls and standing screens. His observations on landscape painting were collected and published by his son Kuo Ssu under the title *Lin-ch'uan kao-chih* ("Lofty Record of Forests and Streams").

While the monumental realistic tradition was reaching its climax, quite another approach to painting was being expressed by a group of intellectuals that included the poet-statesman-artist Su Shih (or Su Tung-p'o), the landscape painter Mi Fei (Mi Fu), the bamboo painter Wen T'ung, the plum painter and priest Chung-jen Hua-kuang, and the figure and horse painter Li Kung-lin. Su and Mi, together with their friend Huang T'ing-chien, were also the foremost calligraphers of the dynasty, all three developing the tradition established by Chang Hsü, Yen Chen-ch'ing, and Huai-su in the mid-8th century. The aim of these artists was not to depict nature realistically—that could be left to the professionals—but to express themselves, to "satisfy the heart." They spoke of merely "borrowing" the forms of things in which for the moment to "lodge" their thoughts and feelings. In this amateur painting mode of the scholar-official (*shih-ta-fu hua,* later called *wen-jen hua*), skill was suspect because it was the attribute of the professional and court painter. The scholars valued spontaneity above all, even making a virtue of awkwardness as a sign of the painter's sincerity.

Mi Fu, an influential and demanding connoisseur, was the first major advocate and follower of Tung Yüan's boneless style, reducing it to mere ink dots (Mi *tien,* or "Mi dots"). This new technique influenced many painters, including Mi Fu's son Mi Yu-jen, who combined it with a subdued form of ink-splashing. Wen T'ung and Su Tung-p'o were both devoted to bamboo painting, an exacting art form very close in technique to calligraphy. Su Tung-p'o wrote poems on Wen T'ung's paintings, thus helping to establish the unity of the three arts of poetry, painting, and calligraphy that became a hallmark of the *wen-jen hua.* When Su Shih painted landscapes, Li Kung-lin sometimes put in the figures. Li was a master of *pai-miao* (plain line) painting, without colour, shading, or wash. He brought a scholar's refinement of taste to a tradition theretofore dominated by Wu Tao-tzu's dramatic style.

The emperor Hui-tsung as patron of the arts

The northern emperors were enthusiastic patrons of the arts. Hui-tsung, perhaps the most knowledgeable of all Chinese emperors about the arts, was himself an accomplished calligrapher (he developed a unique and extremely elegant style known as "slender gold") and a painter chiefly of birds and flowers in the realistic tradition stretching back to Huang Ch'üan and developed by subsequent court artists such as Ts'ui Po of the late 11th century. While meticulous in detail, his works were subjective in mood, following poetic themes that were calligraphically inscribed on the painting. A fine example of the kind of painting attributed to him is the minutely observed and carefully painted "Five-coloured Parakeet on Blossoming Apricot Tree" (Museum of Fine Arts, Boston).

Among the distinguished academicians at Hui-tsung's court were Chang Tse-tuan, whose extraordinarily realistic "Ching-ming Festival" scroll (Palace Museum, Peking) preserves a wealth of social and architectural information in compellingly artistic form, and Li T'ang, who fled to the south in 1127 and supervised the reestablishment of the northern artistic tradition at the new court in Hang-chou. Although Kuo Hsi's style remained popular in the north after the Chin occupation, Li T'ang's mature style came to dominate in the south. Li was a master in the Fan K'uan tradition, but he gradually reduced Fan's monumentality into more refined and delicate compositions and transformed Fan's small "raindrop" texture into a broader "axe-cut" texture stroke that subsequently remained a hallmark of most Chinese court academy landscape painting.

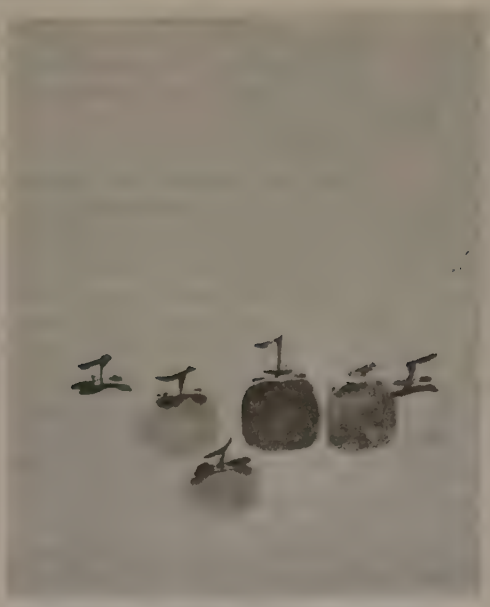
In the first two generations of the Southern Sung, however, historical figure painting regained its earlier dominance at court. Kao-tsung and Hsiao-tsung, respectively the son and grandson of the imprisoned Hui-tsung, sought to legitimize their necessary but technically unlawful assumption of power by supporting works illustrating the ancient classics and traditional virtues. Such works, by artists including Li T'ang and Ma Ho-chih, often include lengthy inscriptions purportedly executed by the emperors themselves. They represent the finest survival today of the ancient court tradition of propagandistic historical narrative painting in a Confucian political mode.

The Ma-Hsia school of painting

Subsequently, in the late 12th and early 13th centuries, the primacy of landscape painting was reasserted. The tradition of Li T'ang was turned, however, in an increasingly romantic and dreamlike direction by the great masters Ma Yüan, his son Ma Lin, Hsia Kuei, and Liu Sung-nien, all of whom served with distinction in the painting division of the Imperial Hanlin Academy. These artists used the Li T'ang technique, only more freely, developing the so-called "large axe-cut" texture stroke. Their compositions are often "one-cornered," depicting a foreground promontory with a fashionably rusticated building and a few stylish figures separated from the silhouettes of distant peaks by a vast and aesthetically poignant expanse of misty emptiness—a view these painters must have seen any summer evening as they gazed across Hang-chou's West Lake. The Ma family's works achieved a philosophically inspired sense of quietude, while Hsia Kuei's manner was strikingly dramatic in brushwork and composition. The Ma-Hsia school, as it came to be called, was greatly admired in Japan during the Muromachi and Momoyama periods, and its impact can still be found today in Japanese gardening traditions.

Toward the end of this period, Ch'an (Zen) Buddhist painting experienced a brief but remarkable florescence, stimulated by scholars abandoning the decaying political environment of the Southern Sung court for the monastic life practiced in the hill-temples across the lake from Hang-chou. The court painter Liang K'ai had been awarded the highest order, the Golden Girdle, between 1201 and 1204, but he put it aside, quit the court, and became a Ch'an recluse. What is thought to be his earlier work has the professional skill expected of a colleague of Ma Yüan, but his later paintings became freer and more spontaneous.

The greatest of the Ch'an painters was Mu-ch'i, or Fa-ch'ang, who reestablished the Liu-t'ung Monastery in the western hills of Hang-chou. The wide range of his work (which included Buddhist deities, landscapes, birds and animals, flowers and fruit) and the spontaneity of his style bear witness to the Ch'an philosophy that the "Buddha essence" is in all things equally and that only a spontaneous style can convey something of the sudden awareness that comes to the Ch'an adept in his moments of illumination. Perhaps his best-known work is his hastily sketched "Six Persimmons" (preserved and idolized in Japan), while a somewhat more conservative style is seen in his triptych



"Six Persimmons," hanging scroll attributed to Mu-ch'i (active mid-13th century), Southern Sung dynasty. Ink on paper. In the Daitoku Temple, Kyōto, Japan. Width 36.2 cm.

Daitoku-ji, Kyoto, photograph, Zen Cultural Laboratory

of three hanging scrolls with Kuan-yin flanked by a crane and gibbons (Daitoku Temple, Kyōto, Japan). Chinese connoisseurs disapproved of the rough brushwork and lack of literary content in Mu-ch'i's paintings, and none appears to have survived in China. His work, and that of other Ch'an artists such as Liang K'ai and Yü-chien, was collected and widely copied in Japan, however, forming the basis of the Japanese *sumi* tradition.

Ch'an Buddhism borrowed greatly from Taoism, both in philosophy and in painting manner. One of the last great Sung artists was Ch'en Jung, an official, poet, and Taoist who specialized in painting the dragon, a symbol both of the emperor and of the mysterious all-pervading force of the Tao. Ch'en Jung's paintings show these fabulous creatures emerging from amid rocks and clouds. They were painted in a variety of strange techniques, including rubbing the ink on with a cloth and spattering it, perhaps by blowing ink onto the painting.

High point in the history of Chinese pottery

Ceramics. The Sung dynasty marked a high point in the history of Chinese pottery, when technical mastery, refinement of feeling, and a natural spontaneity of technique were more perfectly balanced than at any time in Chinese history. The beauty of Sung wares, derived from the simplicity of the shapes and purity of glaze tone and colour, is not a lifeless perfection such as marks the palace wares of the Ch'ing dynasty; in Sung wares the touch of the potter's hand can still be perceived, and glazes have a depth and warmth that was later lost when a higher level of manufacturing skill was attained.

It is convenient to group Sung wares geographically: the chief northern wares are Ting, Ju, Chün, northern celadon, Tz'u-chou, and brown and black glazed wares; those of southern China include Ching-te-chen whiteware (*ying-ch'ing*, or *ch'ing-pai*), Chi-chou wares, celadons, and black wares of Fukien. However, many new kiln sites have been located, and it is now known that one kiln often produced several quite different wares, and decorated stonewares named from the principal factory at Tz'u-chou in southern Hopeh were made in many kilns across the breadth of northern China.

White porcelain made at Chien-tz'u-ts'un in south-central Hopeh was already being produced for the northern courts in the Five Dynasties and continued as an Imperial ware to the beginning of the 12th century. Very finely potted and sometimes decorated with freely incised plants, fish, and birds under the glaze or later with mold-made designs in relief, this Ting ware is directly descended from the northern whitewares of the T'ang dynasty. Supposedly because of Hui-tsung's dissatisfaction with Ting ware, it was replaced in the late Northern Sung by another official ware known as Ju, the rarest and most highly prized of all Chinese ceramics (until recently, only some 60 examples were known). Representing Hui-tsung's celebrated aestheticism, the low-fired Ju stoneware is distinguished by a seemingly soft, milky glaze of pale blue or grayish green with hair-thin crackle. The glaze covers a pale gray or buff body that is usually simple in shape yet highly sophisticated and exquisitely tasteful in effect. Ju ware was produced for only a few years before Hui-tsung's sudden demise. The Ju kilns defied identification until 1986, when they, along with the remains of a workshop, were located at Ch'ing-liang-ssu, more than 160 kilometres southwest of the capital. Another 37 intact examples were soon afterward excavated there. Typical of other kilns, the Ju kilns varied their productions, turning out Tz'u-chou stoneware and Yao-chou-type celadons like those discovered at Yao-an, north of Sian.

Chün stoneware

A sturdy stoneware covered with a thick lavender-blue glaze was made at Chün-chou in Honan. This Chün ware is sometimes marked with splashes of purple or crimson produced by copper oxide. On the finest Chün wares, which are close to Ju in quality, these splashes are used with restraint, but on later Chün-type wares manufactured at Ching-te-chen and near Canton too much purple often gives vessels or flowerpots a mottled, lurid hue that Ming connoisseurs were wont to label "mule's liver" or "horse's lung."

Somewhat related to Chün wares are sturdily potted jars, vases, and bowls with lustrous black or brown glazes. Those that are decorated with flowers and leaves painted in an oxidized rust brown constitute an enormous family of Tz'u-chou wares made for domestic and funerary use in numerous northern China kilns, and they are still being produced in some factories today. Tz'u-chou techniques of decoration included free brush painting under the glaze, carving or scratching (sgraffito work) through one slip to another of a different colour, and painting over the glaze in low-fired colours. The earliest known example of overglaze painting in the history of Chinese pottery bears a date equivalent to 1201. In both the variety and the vigour of their forms and decoration, Tz'u-chou stonewares present a strong contrast to the restraint and exquisite taste of the courtly wares.

Tz'u-chou stoneware vase probably from Chü-lu-hsien, Hopeh province, early 12th century, Northern Sung or Chin dynasty. Dragon decor with white and engraved black slip. In The Nelson-Atkins Museum of Art, Kansas City, Mo., U.S. Height 56.7 cm.

The Nelson-Atkins Museum of Art, Kansas City, Missouri; purchase: Nelson Trust (36-116)

South China wares

After the Sung capital was reestablished at Hang-chou, the finest wares obtainable were once more supplied to the court. These southern *kuan* wares were made for a short time in kilns close to the palace under the direction of the Office of Works. Later, the kilns were established near the altar for sacrifices to heaven and earth, Chiao-t'an, outside the south gate of the city. Chiao-t'an *kuan* ware had a dark opaque body and a beautiful bluish gray layered glaze. A deliberately formed crackle, caused by the shrinking of the glaze as the vessel cooled after firing, is the only ornament on this exquisite ware.

The southern *kuan* was the finest of a huge family of celadons produced in an increasing number of kilns in southeastern China. Lung-ch'üan in southern Chekiang made a fine celadon with bluish green glaze, the best of which was almost certainly supplied to the court and may hence be classed as *kuan*. A variant with strongly marked crackle became known as *ko* ware in deference to the tradition that it was made by the elder brother (*ko*) of the director of the Lung-ch'üan factory. Among the wide range of shapes made in Sung celadon are those derived from forms of archaic bronzes, such as *li, ting,* and *tsun,* testifying to the increasingly antiquarian taste of court and gentry.

Meanwhile, a small factory at Ching-te-chen in Kiangsi was growing to meet the vast increase in the population of southern China. In the Sung, its most characteristic ware was a fine, white, sugary porcelain covered with a transparent, slightly bluish glaze; the ware has been known since Sung times as *ch'ing-pai* ("bluish white") but is called by modern Chinese dealers *ying-ch'ing* ("shadowy blue"). *Ch'ing-pai* ware is very thinly potted, the decoration carved in the clay body or applied in raised slip or beading under the glaze. Sung *ch'ing-pai* wares are the predecessors of a vast output of fine white Ching-te-chen porcelain that was to dominate the Chinese pottery industry during the Yüan, Ming, and Ch'ing dynasties. Other whitewares were made at Yung-ho near Chi-an in Kiangsi.

Kilns in the wooded hills around Chien-yang in northern Fukien produced almost nothing but heavily potted stoneware teabowls covered with a thick black glaze. The finest and rarest of these Chien ware bowls have streaky "hare's fur" or iridescent "oil spot" effects that were much prized by Japanese tea masters, who called this ware *temmoku* after T'ien-mu, the sacred Buddhist mountain in Chekiang province that was near the port from which the ware was shipped to Japan. Yung-ho kilns also turned out a coarse variety of *temmoku* and experimented with novel decorative effects produced by laying floral paper cuts or skeleton leaves under the glaze before firing.

Textiles. Lacking a Sung Shōsō-in repository for decorative arts, knowledge of the textiles of this period is even sketchier than knowledge of those of the T'ang. The main Sung achievement was the perfecting of *k'o-ssu,* an extremely fine silk tapestry woven on a small loom with a needle as a shuttle. The technique appears to have been invented by the Sogdians in Central Asia, improved by the Uighurs, and adapted by the Chinese in the 11th century. The term *k'o-ssu* (literally "cut silk") derives from vertical gaps between areas of colours, caused by the weft threads not running right across the width; it has also been suggested that the word is a corruption of the Persian *qazz* or Arabic *khazz,* referring to silk and silk products. *K'o-ssu* was used for robes, silk panels, and scroll covers and for translating painting into tapestry. In the Yüan dynasty, panels of *k'o-ssu* were exported to Europe, where they were incorporated into cathedral vestments.

K'o-ssu silk tapestry

Yüan dynasty (1206–1368). Although the Mongol conquest made China part of an empire that stretched from Korea to Hungary and opened its doors to foreign contacts as never before, this short-lived dynasty was oppressive and corrupt. Its later decades were marked by social and administrative chaos in which the arts received little official encouragement. The Mongols distrusted the Chinese intelligentsia, relying primarily on Central Asians for government administrative functions. Nevertheless, some influential Chinese writers recognized that the Mongols brought a sense of martial discipline that was lacking in the Sung, and after 1286 an increasing number of Chinese scholars were persuaded to enter government service, undoubtedly hoping to influence their rulers to adopt a more benign policy toward the Chinese people.

Architecture. Little remains of Yüan architecture today. The great palace of Kublai Khan in the Yüan capital Ta-tu ("Great Capital"; now Peking) was entirely rebuilt in the Ming dynasty. Excavations demonstrate that the Yüan city plan is largely retained in that of the Ming; originally conceived under the combined influence of Liu Ping-chung and non-Chinese Muslims such as Yeheidie'er, it appears to be thoroughly Chinese in concept. More detailed information survives only in first-generation Ming dynasty court records and in the somewhat exaggerated description of Marco Polo. This architecture was probably little advanced in point of building technique over those of the Liao and Chin palaces on which they were modeled. The ornate features of their roofs, their bracketing systems, the elevated terraces, and the tight juxtaposition of the buildings are reflected in architectural paintings of the period by such artists as Wang Chen-p'eng, Hsia Yung, and Li Jung-chin. Perhaps the only original Yüan buildings in Peking today are the Drum Tower to the north of the city and the White Pagoda built by Kublai in the stupa form most commonly seen today in the Tibetan *chorten.* The Mongols were ardent converts to Tibetan Buddhism and tolerant of the Taoists, but they seem to have found existing temples enough for their purposes, for they made few new foundations.

Detail of the marble relief of a guardian king on Chü-yung-kuan Gate, Peking, 1345, Yüan dynasty.

Flores-cence of Buddhist sculpture

Sculpture. Buddhist sculpture was one of the few arts that flourished under the patronage of the Mongols, who inherited craftsmen and techniques from the Chin. Yüan style is thus a continuation of the northern tradition, marked by a rather more emphatic modeling and greater richness of detail. A richly sculptured marble gate, constructed in 1342–45 at the Chü-yung Pass between Peking and the Great Wall to the north, boldly illustrates in shallow relief a variety of Buddhist and Taoist divinities and guardian figures; it represents perhaps the finest sculptural work of this or any later period. At this time esoteric Tantric sects were popular, and their complex iconography demanded images with multiple arms and attributes. Some especially fine, realistic Buddhist bronzes may be attributed to a special government department responsible for image casting by the lost-wax process. The dry lacquer technique, invented before the T'ang dynasty, was

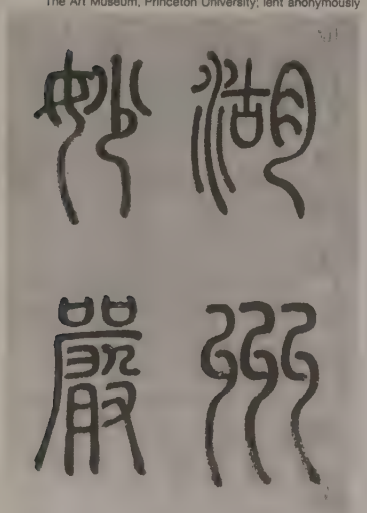
"Twin Pines and Level View," detail of right half of a hand scroll by Chao Meng-fu (1254–1322), Yüan dynasty. Ink on paper. In The Metropolitan Museum of Art, New York City. Size of entire hand scroll 26.7 cm × 1.07 m.

popularized in the Yüan dynasty by the master craftsman Liu Yüan, a scholar and Taoist who made a deep study of Indian iconography before executing the deities for a temple commissioned by the emperor in 1270.

Painting and calligraphy. One school that flourished under Yüan official patronage was that of Buddhist and Taoist painting; important wall paintings were executed at the Yung-lo Temple in Shansi (now restored and moved to Jui-ch'eng). A number of royal patrons, including Kublai, the emperors Buyantu and Tog-temür, and Kublai's great-granddaughter Sengge, built an Imperial collection of important early works and also sponsored paintings that emphasized such themes as architecture and horses. Still, their activities were not a match for Sung royal patronage, and it was in this period that the amateur art of painters of the scholar class (in the tradition of Su Shih and his late Northern Sung colleagues) first came to dominate Chinese painting standards.

The restriction of the scholars' opportunities at court and the choice of many of them to withdraw into seclusion rather than serve the Mongols created a heightened sense of class identity and individual purpose, which in turn inspired their art. Eremitic rather than courtly values now shaped the art of painting as never before, and a stylistic gulf sprang up between literati painters and court professionals that was not bridged until the 18th century. Whereas most painting had previously displayed technical refinement and had conservatively transmitted the heritage of the immediate past, gradually evolving through modest individual departures, the literati thenceforth typically based their styles on a wide-ranging knowledge of distant stylistic precedents, selectively chosen and radically transformed by means of expressive calligraphic brushwork. Style and subject were both intended to reflect closely the artist's own personality and mood rather than conforming to the wishes of a patron. Typical were the simply brushed orchid paintings of Cheng Ssu-hsiao, who painted this traditional symbol of political loyalty without any ground beneath as a comment on the grievous loss of China to foreign domination.

The Art Museum, Princeton University; lent anonymously



"Record of the Miao-yen Temple in Hu-chou," seal script by Chao Meng-fu, *c.* 1309–10, Yüan dynasty. Detail of frontispiece of a hand scroll, ink on paper. In The Art Museum, Princeton University, New Jersey, U.S. Height 35.2 cm.

Ch'ien Hsüan was among the first to define this new direction. From Wu-hsing in Chekiang, he steadfastly declined an invitation to serve at court, as reflected in his painting style and themes. A conservative painter before the Mongol conquest, especially of realistic flowers and birds, he altered his style to incorporate the primitive qualities of ancient painting, favouring the T'ang blue-and-green manner in his landscape painting, stiff or peculiarly mannered renditions of vegetation and small animals, and the archaic flavour of clerical script in his brushwork. Calligraphy became a part of his design and frequently confirmed through historical references a link between subject matter and his eremitic choice of lifestyle. Like many Chinese scholars who espoused this amateur ideal, Ch'ien Hsüan was obliged by demeaning circumstances to exchange his paintings in return for his family's livelihood.

The painter and calligrapher Chao Meng-fu

The most distinguished of the scholar-painters was Chao Meng-fu, a fellow townsman and younger follower of Ch'ien Hsüan who became a high official and president of the Imperial Hanlin Academy. In his official travels he collected paintings by Northern Sung masters that inspired him to revive and reinterpret the classical styles in his own fashion. A notable example is "Autumn Colours in the Ch'iao and Hua Mountains" (1296; National Palace Museum, Taipei), a nostalgic, deliberately archaistic landscape in the T'ang manner. The hand scrolls "Twin Pines and Level View" (The Metropolitan Museum of Art, New York City) and "Water Village" (1302; Palace Museum, Peking) exemplify his reinterpretation of past masters (Li Ch'eng and Tung Yüan, respectively) and furthered the new direction of scholarly landscape painting by applying the standards and techniques of calligraphy to painting.

The Yüan produced many fine calligraphers, including Chao Meng-fu, who was the most influential, Yang Wei-chen, and Chang Yü. The period was less innovative in calligraphy than in painting, however, and Chao's primary accomplishment was to sum up and resynthesize the past. His well-studied writing style was praised in his time for its breadth of historical understanding, and his standard script became the national model for book printing, but he was later criticized for a lack of daring or expression of personality, for a brush style too sweet and pleasing.

Other gentlemen-painters who worked at the Yüan court

perpetuated more conservative Sung styles, often rivaling or even surpassing their Sung predecessors in the process. Jen Jen-fa worked in great detail and was perhaps the last of China's great horse painters; he defended his court service through both the style and theme of his paintings. Li K'an carefully studied the varieties of bamboo during his official travels and wrote a systematic treatise on painting them; he remains unsurpassed as a skilled bamboo painter. Kao K'o-kung followed Mi Fu and Mi Yu-jen in painting cloudy landscapes that symbolized good government. Wang Mien, who served not the Mongols but anti-Mongol forces at the end of the dynasty, set the highest standard for the painting of plums, a symbol of irrepressible purity and, potentially, of revolutionary zeal.

Ideals of the retired scholars

In retrospect, however, it was the ideals of the retired scholars that had the most lasting effect on later Chinese art. This may be summed up as individuality of expression, brushwork more revealing of the inner spirit of the subject—or of the artist himself—than of outward appearance, and suppression of the realistic and decorative in favour of an intentional plainness, understatement (*p'ing-tan*), and awkwardness (*cho*), which marks the integrity of the gentleman suspicious of too much skill. Four masters of the middle and later Yüan, all greatly influenced by Chao Meng-fu, came to be regarded as the foremost exponents of this philosophy of painting in the Yüan period. Huang Kung-wang, a Taoist recluse, was the oldest. His most revered and perhaps only authentic surviving work is the hand scroll "Dwelling in the Fu-ch'un Mountains" (National Palace Museum, Taipei), painted with dynamic brushwork during occasional moods of inspiration between 1347 and 1350. Wu Chen was a poor Taoist diviner, poet, and painter who, like Huang Kung-wang, was inspired by Tung Yüan and Chü-jan, whose manner he rendered, in landscapes and bamboo painting alike, with blunt brushwork, minimal motion, and utmost calm.

The third of the Four Masters of the Yüan dynasty was Ni Tsan, a prosperous gentleman and bibliophile forced by crippling taxation to give up his estates and become a wanderer. As a landscapist he eliminated all depictions of human beings. He thus reduced the compositional pattern of Li Ch'eng (symbolizing lofty gentlemen in isolation from the court) to its simplest terms, achieving as Wu Chen had a sense of austere and monumental calm with the slenderest of means. He used ink, it was said, as sparingly as if it were gold. Quite different was the technique of the fourth Yüan master, Wang Meng, a grandson of Chao Meng-fu. His brushwork was dense and energetic, derived from Tung Yüan but tangled and hoary and thereby imbued with a feeling of great antiquity. He often drew heavily from Kuo Hsi or from what he perceived as T'ang traditions in his landscape compositions, which he filled with scholarly retreats. He sometimes used strong colours as well, which added a degree of visual charm and nostalgia to his painting that was lacking in the other three masters' work.

Models for later scholar-painters

The combination in the Four Masters of a consistent philosophical and political attitude and a wide range of ink techniques made them models for later scholar-painters, both in their lives and in their art. It is impossible to appreciate the work of the landscape painters of the Ming and Ch'ing dynasties unless one is aware of how acutely conscious they were of their debt to the Yüan masters and how frequently they paid tribute to them both in their style and in their inscriptions. Thenceforward, indeed, the artist's own inscription, as well as the colophons of admirers and connoisseurs, became an integral part of the total work of art.

Ceramics. It is a paradox that the Mongol occupation, while it destroyed much, also shook China free from the static traditions and techniques of the late Southern Sung and made possible many innovations, both in painting and in the decorative arts. The north was least progressive, and the main centre of pottery activity shifted permanently to the south. The northern traditions of Chün and Tz'u-chou ware continued through the Chin and Yüan, bolder but coarser than before. New shapes included a heavy, wide-mouthed jar, sometimes with decoration boldly carved through a black or brown slip or painted in two or three

colours. These new techniques and the overglaze painting already developed in the Chin dynasty prepared the way for the three- and five-colour wares of the Ming.

While no Yüan celadon has the perfection of colour of Sung *kuan* and Lung-ch'üan wares, being more olive-green in tone, the quality is high. And the variety of decorative techniques is far wider than that of the Sung. These include raised relief designs molded under the glaze, fish and dragons raised "in the biscuit" (that is, unglazed) in relief, and iron-brown spots that the Japanese call *tobi seiji* ("flying celadon"). Vases and dishes were now sturdily potted in porcelain, often mold-made, and of considerable size.

Factories at Ching-te-chen were expanding rapidly. While their products included celadon, their chief output, as before, was white porcelain, including richly modeled figurines of Kuan-yin and other Buddhist deities. *Ch'ing-pai* was now decorated with floral motifs and beading in raised relief or incised under the glaze, the most elaborate pieces combining flowers and vines in appliqué relief with openwork panels. A stronger, less sugar-white porcelain with molded or incised decoration was produced—called *shu-fu* ware from the presence of these characters (perhaps referring to a central government agency) under the thick, unctuous glaze.

Use of cobalt blue

The earliest evidence of the use of cobalt blue, probably imported from the Middle East, is seen in its application as an underglaze pigment on fragments dating to the late 8th or early 9th century that were unearthed at Yang-chou in 1983. The occasional use of underglazed cobalt continued in the Northern Sung. It was not until the Yüan dynasty, however, that underglazed blue decoration began a rapid rise in popularity. It was applied on fine white porcelains of the *shu-fu* type and combined with Islāmic decorative taste. These blue-and-white wares soon became the most popular of all Chinese ceramics, both at home and abroad. A pair of richly ornate temple vases dated 1351 (in the Percival David Foundation in London) are proof that the technique was fully mastered by that time. The finest Ching-te-chen examples were reserved for the court, but coarse varieties were made in southern China for trade with Southeast Asia or for export to the Middle East. Experiments also were made with painting in underglaze copper red, but it was difficult to control and soon abandoned.

Lacquerwork. While lacquer continued to be made in bolder versions of the undecorated T'ang and Sung shapes, notable advances included incising and engraving and filling the lines with gold leaf or silver powder. The most important innovation was the carving of pictorial designs, floral patterns, or dragons through a thick coating of red or, less frequently, black lacquer. A connoisseur's manual, *Ko ku yao lun* ("Essential Criteria of Antiquities") by Ts'ao Chao, says that at the end of the Yüan dynasty Chang Ch'eng and Yang Mao, pupils of Yang Hui, were noted for this technique.

Ming dynasty (1368–1644). The restoration of a native dynasty made China once more a great power. Ming felt a kinship with the heyday of the T'ang dynasty that is reflected in the vigour and rich colour of Ming arts and crafts. Early in the 1400s, China again expanded into Central Asia, and maritime expeditions brought Central Asian products around the Indian Ocean to its own shores. Chinese pottery exports also greatly increased. The 15th century was a period of settled prosperity and great achievement in the arts, but the last century of the dynasty was marked by corruption at court and deep discontent among the scholar-gentry that is reflected in their painting.

Architecture. The first Ming emperor established his capital at Nanking (Nan-ching, "Southern Capital"), surrounding it with a wall more than 30 kilometres in length, one of the longest in the world. The palace he constructed no longer exists. In 1402, a son of the founding Ming emperor enfeoffed at the old Yüan capital usurped the throne from his nephew, the second Ming ruler, and installed himself as the Yung-lo Emperor. He rebuilt the destroyed Mongol palaces and moved the Ming capital there in 1421, renaming the city Peking (Pei-ching, "Northern Capital"). His central palace cluster, the Forbidden City, is the foremost surviving Chinese palace compound, maintained and successively rebuilt over the centuries. In a strict hierarchical sequence, the palaces lie centred within the bureaucratic auspices of the Imperial City, which is surrounded by the metropolis that came to be called the "inner city," in contrast to the newer (1556) walled southern suburbs, or "outer city." A series of eight major state temples lay on the periphery in balanced symmetry, including temples to the sun (east) and moon (west) and, to the far south of the city, the huge matched temple grounds of heaven (east) and agriculture (west). Close adherence to the traditional principles of north-south axiality, walled enclosures and restrictive gateways, systematic compounding of courtyard structures, regimentation of scale, and a hierarchy of roofing types were all intended to satisfy classical architectural norms, displaying visually the renewed might of native rulers and their restoration of traditional order.

The Forbidden City

Central to this entire arrangement are three great halls of state, situated on a high, triple-level marble platform (the number three, here and elsewhere, symbolic of heaven and of the Imperial role as chief communicant between heaven and earth). The southernmost of these is the largest wooden building in China (roughly 65 by 35 metres), known as the Hall of Supreme Harmony. (The names and specific functions of many of the main halls were changed several times in the Ming and Ch'ing.) To their north lies a smaller-scale trio, the main halls of the Inner Court, in which the emperor and his ladies resided. The entire complex now comprises some 9,000 rooms (of an intended 9,999, representing a perfect yang number). The grandeur of this palatial scheme was matched by the layout of a vast Imperial burial ground on the southern slopes of the mountain range to the north of Peking, not far from the Great Wall, which eventually came to house 13 royal mausoleums, with an elaborate "spirit way" and accompanying ritual temple complexes.

In its colossal scale, the monumental sweep of its golden-tiled roofs, and its axial symmetry, the heart of the Forbidden City is unsurpassed as a symbol of Imperial power. In architectural technique, however, the buildings represent a decline from the adventurous planning and construction of the Sung period. Now the unit is a simple square or rectangular pavilion with few projections or none, and the bracketing system is reduced to a decorative frieze with little or no structural function. Instead, emphasis is placed upon carved balustrades, rich colour, and painted architectural detail. This same lack of progress shows in Ming temples also. Exceptional is the Hall of Prayer for Good Harvests (Ch'i-nien Tien) at the Temple of Heaven, a descendant of ancient state temples like the Ming-t'ang. It took its present circular form about 1530. Its three concentric circles of columns, which range up to 18 metres in height, symbolize the 4 seasons, the 12 months, and the 12 daily hours; in a remarkable feat of engineering, they support the three roof levels (a yang number) and, in succession, a huge square brace representing earth, a massive circular architrave denoting heaven, and a vast interior cupola decorated with golden dragons among clouds. (In its final rebuilding, in the 1890s, its tall timbers had to be imported from Oregon, U.S.)

Painting. The first Ming emperor was a highly distrustful personality whose vengeful focus fell upon Su-chou, the local base of his chief rival for the throne as well as home to the Yüan period literati painting movement. So many artists became victim to his recriminations, typically for political rather than artistic reasons, that this novel movement in Chinese painting history was nearly halted. Among those literati painters who lost their lives in this manner were Wang Meng, Chao Yüan, Hsü Pen, Ch'en Ju-yen, Chang Yü, Chou Wei, and Sheng Chu. Rejecting the individualist standard of literati painting, early Ming emperors who revived the custom of summoning painters to court sought instead to create a cultural bridge to the last native regimes, the Tang and Sung. Although they revived Sung professional court styles, they never organized their painters into a central teaching academy and indeed sometimes dealt quite harshly with them. Scholar-painters, increasingly few in number in the early Ming, stayed at home in the south, further widening the gulf between themselves and court artists.

Court painters

Early Ming court painters such as Hsieh Huan and Li Tsai at first revived the T'ang blue-and-green and Northern Sung court styles of Kuo Hsi. Pien Wen-chin and his follower Lü Chi carried forward the bird and flower painting tradition of Huang Ch'üan, Ts'ui Po, and the Sung emperor Hui-tsung. Gradually, however, the Southern Sung styles of the landscape artists Li T'ang, Ma Yüan, and Hsia Kuei came to hold sway, beginning with Tai Chin, who served under the fifth emperor, the Hsüan-te Emperor (himself a painter of moderate ability). Nevertheless, Tai Chin, who was opposed in the Peking capital by jealous court rivals and who found the restrictions there intolerable (as did many others who followed), was affected by the calligraphically inspired scholars' art: his brushwork shows far greater freedom than is found in his Southern Sung models.

Like Tai Chin, many professional painters came to Peking from the old Southern Sung capital region around Hangchou, and they were said to belong to the Che school of painting. Many of the so-called Che school artists were in fact scholars disgruntled with the autocratic Ming politics and drawn to Taoist eremitic themes and eccentric brushwork. Most dazzling among them, perhaps, was Wu Wei, whose drunken bouts at court were forgiven out of admiration for his genius with the brush.

Among the few important amateur painters to hold a scholarly position at the early Ming court was Wang Fu, who survived a long period of banishment to the frontier under the first emperor to return as a court calligrapher. He became a key figure in the survival and transmission of Yüan literati style and the first to single out the masters Huang Kung-wang, Wu Chen, Ni Tsan, and Wang Meng as models. Other early Ming scholar-official painters in the Yüan tradition were the bamboo painter Hsia Ch'ang and Liu Chüeh.

The Wu school of landscape painting

The Wu district of Kiangsu, in which Su-chou lies, gave its name to the Wu school of landscape painting, dominated in the late 15th century by Liu Chüeh's friend and pupil Shen Chou. Shen Chou never became an official but devoted his life to painting and poetry. He often painted in the manner of the Yüan masters, but his interpretations of Ni Tsan and Wu Chen are more clearly structured, firmer in brushwork, and unsurpassed in all Chinese art for their humane feeling, while the gentle and unpretentious figures he introduced give his paintings great appeal. Shen Chou commanded a wide range of styles and techniques, on which he impressed his warm and vigorous personality. He also became the first to establish among the literati painters a flower painting tradition. These works, executed in the "boneless" fashion developed by 10th-century court artists but with the freedom of such late Sung Ch'an painters as Mu-ch'i, were followed with greater technical versatility by Ch'en Shun and Hsü Wei in the late Ming and then by Shih-t'ao (Tao-chi) and Chu Ta of the early Ch'ing. Their work, in turn, served as the basis for the late-19th–20th-century revival of flower painting.

Shen Chou's younger contemporary and friend Wen Cheng-ming showed an even greater interest in the styles of the past, which he reinterpreted with a refined and scholarly precision. He, too, had many styles and was a distinguished calligrapher. He was an active teacher of painting as well, and among his more gifted pupils were his son Wen Chia and his nephew Wen Po-jen. Their landscapes display a lyrical delicacy in composition, touch, and colour, qualities that in lesser late Ming artists of the Wu school degenerated into a precious and artificial style.

Three early 16th-century professional Su-chou masters, Chou Ch'en, Ch'iu Ying, and T'ang Yin, established a standard somewhat different from that of the scholarly Wu group, never renouncing the professional's technical skills yet mastering the literary technique as well. They achieved a wide range, and sometimes a blend, of styles that could hardly be dismissed by scholarly critics and won great popular acclaim. In the succeeding generations, other painting masters similarly helped confuse the distinction between amateur and professional standards, and, in the early 17th century, a number of these also showed the first influence of the European technique that had been brought to China through engravings and then oil paintings by Matteo Ricci and other Jesuit missionaries after 1600. Among these painters were the landscapists Wu Pin from Nanking, Chang Hung from Su-chou, and Lan Ying from Ch'ien-t'ang in Chekiang province. Two who initiated the first major revival of figure painting since Sung times, possibly resulting from the encounter with Western art, were the southern painter Ch'en Hung-shou and the Peking artist Ts'ui Tzu-chung. Perspective and shading effects appear among other naturalistic features in the art of this generation, along with a newfound interest in saturated colours and an attraction to formal distortion, which may have derived in part from a fascination with the unfamiliar in Western art. Beyond the revived interest in naturalism, which seems to have inspired in some artists a renewed attention to Five Dynasties and Sung painting (as the last period in which Chinese artists had displayed knowledge about such matters), there occurred an even more fundamental questioning of contemporary standards and a deep disillusionment that were part of the spirit of this period of national decline. The breakdown of orthodoxy reached an extreme form in Hsü Wei. In his explosive paintings, chiefly of flowers, plants, and bamboo, he showed an absolute mastery of brush and ink and a total disregard of tradition.

Standing above all others of this period in terms of his-

"Poet on a Mountain Top," album leaf mounted as a hand scroll by Shen Chou (1427–1509), Ming dynasty. Ink on paper or ink and light colour on paper. In The Nelson-Atkins Museum of Art, Kansas City, Mo., U.S. 38.7 × 60.2 cm.

Influence of Tung Ch'i-ch'ang

torical impact, the theorist, critic, and painter Tung Ch'i-ch'ang saw the proliferation of styles as a symptom of the decline in morale of the scholar class as the Ming became increasingly corrupt. His aim to reestablish standards in landscape painting paralleled a movement to restore traditional virtue to government. In his brief but influential essay *Hua shuo* ("Comments on Painting"), he set out what he held to be the proper lineage of scholarly painting models, from Wang Wei of the T'ang through Tung Yüan and Chü-jan of the Five Dynasties, Su Shih and Mi Fu of the Sung, and Huang Kung-wang, Wu Chen, Ni Tsan, and Wang Meng of the Yüan to Shen Chou and Wen Cheng-ming. He labeled these artists as "Southern school" in reference to the Southern school of Ch'an Buddhism and its philosophy of spontaneous enlightenment, while he rejected such "Northern school" (*i.e.*, gradualist, pedantic) artists as Kuo Hsi, Ma Yüan, Hsia Kuei, and Ch'iu Ying. Tung believed that the great painting models were highly creative individuals who, to be followed effectively, had to be creatively reinterpreted. Appropriately, his own landscape painting was often quite original, sometimes daringly so, even while based on a systematic reduction and synthetic reintegration of past styles. However, having breathed new life into a troubled tradition by looking inward and to the past, his reinterpretations (particularly of the styles of Tung Yüan and Chü-jan) set an ideal beyond which his contemporaries and followers could not go without either a great leap of imagination, a direct return to nature, or a departure from the historical core of Chinese painting standards. Only a few, in the early Ch'ing, could achieve this.

Woodblock printing

One further feature of late Ming art was the florescence of woodblock printing, including the appearance of a sophisticated tradition of polychrome printing, done in imitation of painting. Among the earliest major examples were the *Fang-shih mo p'u* of 1588 and *Ch'eng-shih mo yüan* of 1606 ("Mr. Fang Yü-lu's Ink Catalog" and "Mr. Ch'eng Ta-yüeh's Ink Garden," respectively), which utilized graphic designs by significant artists to promote the products of Anhwei province's foremost manufacturers of ink sticks. The *Shih-chu-chai shu-hua-p'u* ("Ten Bamboo Studio Manual of Painting and Calligraphy"), produced by Hu Cheng-yen between 1619 and 1633, set the highest standard for polychrome woodblock printing and helped influence the development of colour printing in Japan. Painters such as Ch'en Hung-shou participated in print production in forms ranging from book illustration to playing cards, while others, including Hsiao Yün-ts'ung, generated high-quality topographical illustrations. Through such artists, the medium came to influence painting as well as be influenced by it.

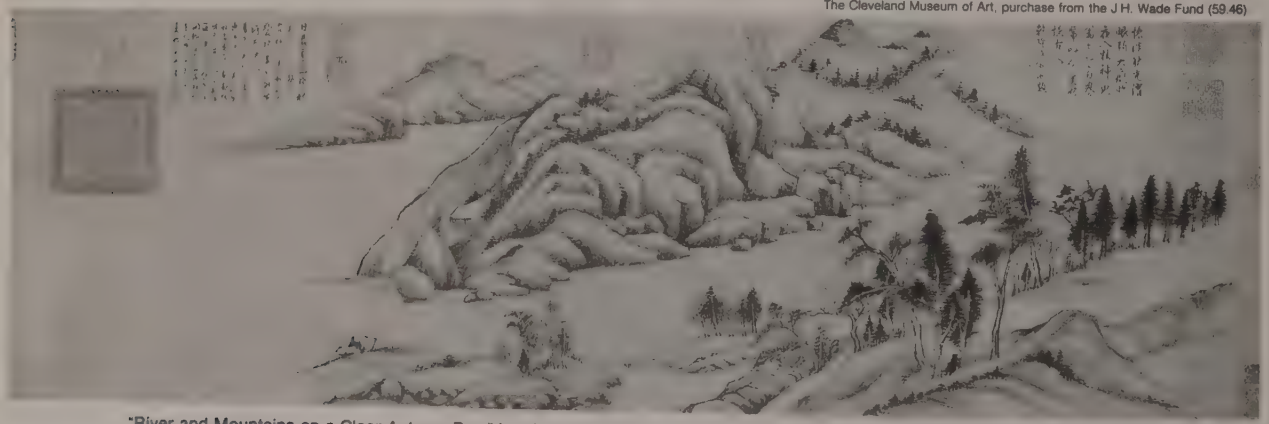
Calligraphy. Calligraphy continued to thrive in the Ming period, especially in the 16th and early 17th centuries, and new developments, such as the appearance of calligraphic hanging scrolls, testified to the increasing popularity of writing as a decorative art form. Tung Ch'i-ch'ang, in calligraphy as in painting, came to be regarded as a leader for his time (sometimes paired with Wen Cheng-ming, of the previous generation). He developed a style as historically conscious as, yet somewhat more individualized than, that of Chao Meng-fu of the Yüan, the previous acknowledged master. But Tung, like Chao, was subjected to criticism for too attractive a style. Furthermore, he was surrounded by numerous middle to late Ming masters who greatly enriched the art of the period with strikingly personal styles (especially in the execution of cursive and semicursive scripts) that showed the influence of the middle T'ang and Northern Sung dynasty individualists. They included Ch'en Hsien-chang, Chu Yün-ming, Ch'en Shun, Wang Wen, Hsü Wei, Chang Jui-t'u, Ni Yüan-lu, Huang Tao-chou, Shih K'o-fa, and Wang To.

Sculpture. There was a great deal of rebuilding and refurbishing of temples in this period of national recovery, but in point of style Ming religious sculpture represents no significant development except in grander scale, greater realism, and richer colours. Colossal figures lining the approaches to early Ming Imperial tombs at Nanking reflect a deliberate revival of T'ang style. More typically Ming are such architectural details as glazed pottery figures decorating roof ridges, whose vigorous modeling is derived from traditions of popular art. The best Ming sculpture is revealed in small ornamental pieces: animals and figures carved in jade, ivory, wood, and other materials, some of the most beautiful of which are Taoist and Buddhist figurines made in ivory-white porcelain at Te-hua in Fukien.

Expansion of pottery production

Ceramics. While northern traditions of Tz'u-chou and Chün ware continued to decline, pottery production in the south expanded. It was chiefly centred on Ching-te-chen, an ideal site because of the abundance of minerals used for porcelain manufacture—china clay and china stone—ample wood fuel, and good communications by water. At Ching-te-chen the relatively coarse-bodied *shu-fu* ware was developed into a hard white porcelain that no longer reveals the touch of the potter's hand. The practically invisible designs sometimes carved in the translucent body are known as *an-hua,* "secret decoration." In the Yung-lo period (1402–24) the practice began of putting the reign mark on the base. This was first applied to the finest white porcelain and to monochrome ware decorated with copper red under a transparent glaze.

In the early decades of the Ming, the repertoire of designs on Yüan blue-and-white was continued and refined. At first, this ware evidently was considered too vulgar for court use, and none bears the Imperial reign mark until the Hsüan-te period (1425–35). By this time the often crowded Yüan patterns had given way chiefly to dragons or floral motifs of great clarity and grace, vigorously applied in a thick, deep-blue pigment to dishes, vases, stem cups, and flattened pilgrim jars. Sometimes a richer effect was achieved by painting dragons in underglaze red on a blue ground or vice versa. In the Ch'eng-hua period (1464–87), the blue-and-white designs became somewhat tenuous and over-refined, and the characteristic wares made for the Cheng-te Emperor (1505–21) and his Muslim eunuchs often bear Arabic inscriptions. In the Chia-ching (1521–67) and Wan-li (1572–1620) periods, the Imperial kilns



"River and Mountains on a Clear Autumn Day," hand scroll by Tung Ch'i-ch'ang (1555–1636), Ming dynasty. Ink on paper. In The Cleveland Museum of Art, Ohio, U.S. 37.9 cm × 1.37 m.

were badly mismanaged, and their products were often of poor quality. Private factories, however, turned out lively wares until the end of the dynasty.

"Chicken cups"

Overglaze painting was applied with delicate care in the Ch'eng-hua period, chiefly in the decoration of small wine cups with chicken motifs, much admired by Chinese connoisseurs. Overglaze painting soon became popular, being applied in the 16th century in stronger colours brilliantly contrasted against a dead-white background. These vigorous (*wu ts'ai*) "five-colour" wares were especially free and bold in the Chia-ching and Wan-li periods. Crude but lively imitations of these and of the blue-and-white of Ching-te-chen, made in southern China kilns partly for the Southeast Asian market, are known as "Swatow ware" from one of the export sites. Among the most impressive of Ming pottery types are the *san ts'ai* ("three-colour") wares, chiefly vases and jars decorated with floral motifs in turquoise, purple, yellow, and deep violet blue, the colours being separated by raised lines in imitation of the metal strips used in cloisonné work (see below). This robust ware was made in several centres, the best of it between 1450 and 1550.

Beginning in the early 16th century, a new ceramic tradition emerged in the town of I-hsing, on the western side of Lake T'ai, catering to the tea taste of scholars in the nearby Su-chou area. Individually made, sometimes to order, rather than mass-produced, I-hsing wares were often signed or even poetically inscribed by highly reputable master craftsmen, such as Shih Ta-pin of the Wan-li era and Ch'en Ming-yüan of the Ch'ing dynasty K'ang-hsi period. The wares were usually unglazed and derived their striking colours—brown, beige, reddish purple, yellow, black, and blue—after firing from the distinctive clays of the region and were known as "purple-sand" teapots. Pieces alternated between two body types: complex floral shapes and exquisitely simple geometric designs.

Metalwork. The technique of cloisonné enamel on a metal base, in which the colours are separated by little metal strips, or walls (cloisons), developed in Byzantium about the 5th century AD and probably reached East Asia in the T'ang dynasty. It seems to have been lost again, however, and reintroduced in the 14th century, when it was referred to in the *Ko-ku yao-lun* as "Ta-shih ware" ("Muslim" ware) and "similar to Fo-lang-k'an" (similar to Byzantine enamelware). While some pieces may have been made for the Yüan court, no Chinese Ming cloisonné has been positively identified as of earlier date than the Hsüan-te Emperor's reign (1425–35), when the reign mark first appears. The decoration of the 15th-century pieces is varied, bold, and free; the brass cloisons are thin; and light and dark blue, red, and yellow predominate among the rich and sometimes rather roughly applied colours. Cloisonné of the Ch'ing dynasty and modern times is more perfectly finished than that of the Ming; the shapes are often more ornate but elaborate and monotonous; and the copper cloisons are more insistent in the decoration.

Decoration of 15th-century cloisonné pieces

Lacquerwork. The carved lacquer first developed in the Yüan dynasty continued through the Ming and Ch'ing and was made in many different factories. It reached a high level in carved red lacquer (*t'i-hung*) dishes, trays, covered boxes, and cups of the Yung-lo and Hsüan-te reigns. Yung-lo reign marks, scratched on with a sharp point, are not reliable, but some pieces, bearing carved and gold-inlaid marks of the Hsüan-te Emperor, may be of the period. Decoration of this early Ming lacquer includes both pictorial designs (landscapes with figures in pavilions are common) and rich dragon, phoenix, and floral motifs, carved deeply in a full, freely flowing and plastic style, often against a yellow background. While this style continued into the 16th century, the Chia-ching period also saw the emergence of more realistic and intricate designs that are shallower and more sharply carved, sometimes through as many as nine layers of different colours, on a background consisting of minute brocade (allover floral and figure designs) or diaper (diamond-shaped) patterns.

Ch'ing dynasty (1644–1911/12). The Manchu conquest did not produce a dislocation of Chinese social and cultural life as had the Mongol invasion. On the contrary, even before their conquest, the Manchus began imitating Chinese ways, and the Ch'ing rulers, particularly K'ang-hsi (1661–1722) and Ch'ien-lung (1735–96), were well-educated men, eager to enlist the support of Chinese scholars. They were extremely conservative in their political and cultural attitudes; and in artistic taste, their native love of extravagance (which the Chinese viewed as "barbarous") was tempered, ironically, by an equally strong conservative propensity. The art of the Ch'ing dynasty, even the painting of many of its finest eccentrics and the design of its best gardens, is similarly characterized both by lavish decoration and ornate effects as well as by superb technique and conservative taste. In the 19th century, however, China's internal weakness and humiliation by the Western powers were reflected in a growing stagnation of the arts.

Architecture. Ch'ing dynasty work in the Forbidden City was confined chiefly to the restoration or reconstruction of major Ming buildings, although the results were typically more ornate in detail and garish in colour than ever before. The Manchu rulers were most lavish in their summer palaces, created to escape the heat of the city. In 1703 the K'ang-hsi Emperor began near the old Manchu capital, Cheng-te, a series of palaces and pavilions set in a natural landscape. Engravings of these made by the Jesuit father Matteo Ripa in 1712–13 and brought by him to London in 1724 are thought to have influenced the revolution in garden design that began in Europe at about this time. Near the Cheng-te palace were built several imposing Buddhist temples in a mixed Sino-Tibetan style that reflects the Tibetan Buddhist leanings of the K'ang-hsi, Yung-cheng, and Ch'ien-lung emperors.

Summer palaces

About 1687 the K'ang-hsi Emperor had begun to create another garden park northwest of Peking, which grew under his successors into the enormous Yüan-ming Yüan ("Garden of Pure Light"). Here were scattered a great number of official and palace buildings, to which the Ch'ien-lung Emperor moved his court semipermanently. In the northern corners of the Yüan-ming Yüan, the Jesuit missionary and artist Giuseppe Castiglione (known in China as Lang Shih-ning) designed for Ch'ien-lung a series of extraordinary Sino-Rococo buildings, set in Italianate gardens ornamented with mechanical fountains designed by the Jesuit priest Michel Benoist. Today the Yüan-ming Yüan has almost completely disappeared, the foreign-style buildings having been burned by the French and British in 1860. To replace it, the empress dowager Tz'u-hsi greatly enlarged the new summer palace (I-ho Yüan) along the shore of K'un-ming Lake to the north of the city.

The finest architectural achievement of the period, however, occurred in private rather than institutional architecture—namely, in the scholars' gardens of southeastern China, in such towns as Su-chou, Yang-chou, and Wu-hsi. As these often involved renovations carried out on Yüan and Ming dynasty foundations, it remains difficult to discern the precise outlines of their innovations. With the aid of paintings and Chi Ch'eng's *Yüan yeh* ("Forging a Garden," 1631–34), it becomes evident that, as in the worst of Ch'ing architecture, these gardens became ever more ornate. The best examples, however, remain well within the bounds of good taste owing to the cultivated sensibility of scholarly taste, and they were distinguished by an inventive imagination lacking in Manchu court architecture. Such gardens were primarily Taoist in nature, intended as microcosms invested with the capacity to engender tranquillity and induce longevity in those who lodged there. The chief hallmark of these gardens was the combination of a central pond, encompassing all the virtues of yin in the Chinese philosophical system, with the extensive use of rugged and convoluted rockery, yang, which summed up the lasting Chinese adoration of great mountain chains through which flowed the vital energy of the earth. (The most precious rocks were harvested from the bottom of Lake T'ai near Su-chou.)

Private scholars' gardens

Throughout this urban garden tradition, where the scale was necessarily small and space was strictly confined, designers attempted to convey the sense of nature's vastness by breaking the limited space available into still smaller but ever varied units, suggesting what could not otherwise literally be obtained, and expanding the viewer's imagina-

tion through inventive architectural design. Among those gardens still preserved today, the Liu Garden in Su-chou offers the finest general design and the best examples of garden rockery and latticed windows, while the small and delicate Garden of the Master of Nets (Wang-shih Yüan), also in Su-chou, provides knowledgeable viewers a remarkable series of sophisticated surprises.

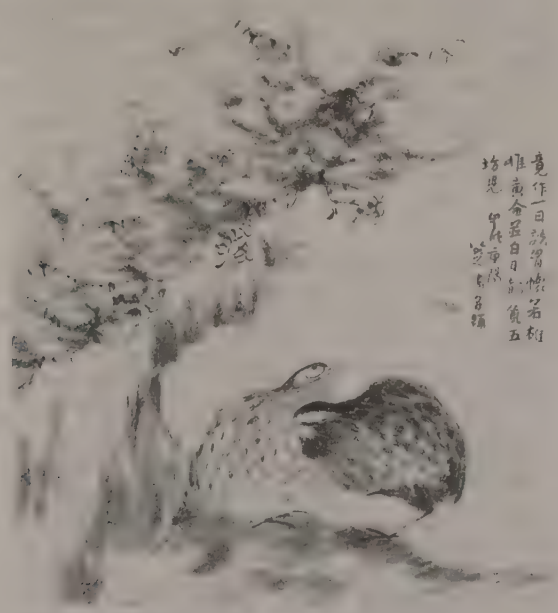
Painting and printmaking. The dual attraction of the Manchu rulers to unbridled decoration and to orthodox academicism characterized their patronage at court. In regard to the former, they favoured artists such as Yüan Chiang, who, in the reign of K'ang-hsi, applied to the model of Kuo Hsi, with great decorative skill, the mannered distortions that had cropped up in the late Ming partly as a result of Ming artists' exposure to an unfamiliar Western art. More thoroughly Westernized work, highly exotic from the Asian perspective, was produced both by native court artists like Chiao Ping-chen, who applied Western perspective to his illustrations of *Keng-chih-t'u* ("Rice and Silk Culture"), which were reproduced and distributed in the form of wood engravings in 1696, and by the Jesuit missionary and painter Giuseppe Castiglione. In the mid-18th century Castiglione produced a Sino-European technique that had considerable influence on court artists such as Tsou I-kuei, but he was ignored by literati critics. His depictions of Manchu hunts and battles provide a valuable visual record of the times.

Ch'ing patronage of the scholar-amateur style of painting

On the other hand, Manchu emperors saw to it that conservative works in the scholar-amateur style by Wang Hui, Wang Yüan-ch'i, and other followers of Tung Ch'i-ch'ang were also well represented at court, largely putting an end to the conflict at court between professional and amateur styles that had been introduced in the Sung and played a significant role in the Ming. In a sense, the amateur style was crowned victor, but it came at the expense of the amateurism that had defined its purpose. This politically effective aspect of Manchu patronage may have been less a specifically calculated strategy than a natural extension of their concerted attempts to cultivate and recruit the scholar class in order to establish their legitimacy.

The Ch'ien-lung Emperor was the most energetic of royal art patrons since Hui-tsung of the Sung, building an Imperial collection of over 4,000 pre-Ch'ing paintings and calligraphy and cataloging them in successive editions of the *Shih-ch'ü pao-chi*. The shortcomings of his taste, however, were displayed in his preference for recent forgeries rather than the originals in his collection (notably, copies of Huang Kung-wang's "Dwelling in the Fu-ch'un Mountains" and of Fan K'uan's "Travelers Among Mountains and Streams") and in his propensity for covering his collected masterpieces with multiple impressions of court seals and calligraphic inscriptions in a mediocre hand.

Sen-oku Hakko kan, Kyoto



"Two Birds," album leaf by Chu Ta (Pa-ta Shan-jen), 1694, Ch'ing dynasty. Ink and slight colour on paper. In the Sumitomo Collection, Sen-oku Hakko kan, Kyōto, Japan. 31.7 × 27.7 cm.

The conservatism of Ch'ing period painting was exemplified by the so-called "Six Masters" of the late 17th–early 18th century, including the so-called "Four Wangs," Wu Li, and Yün Shou-p'ing. In the works of most of these artists and of those who followed their lead, composition became routinized, with little in the way of variation or genre detail to appeal to the imagination; fluency of execution in brushwork became the exclusive basis for appreciation. Wang Shih-min, who had been a pupil of Tung Ch'i-ch'ang, retired to T'ai-ts'ang near modern Shanghai at the fall of the Ming, making it the centre of a school of scholarly landscape painting that included his friend Wang Chien and the younger artist Wang Hui. Wang Hui was a dazzling prodigy whose landscapes included successful forgeries of Northern Sung and Yüan masters and who did not hesitate to market the "amateur" practice, both among fellow scholars and at the Manchu court; however, the hardening of his style in his later years foreshadowed the decline of Ch'ing literati painting for lack of flexible innovation. By contrast, Wang Shih-min's grandson, Wang Yüan-ch'i, was the only one of these six orthodox masters who fully lived up to Tung Ch'i-ch'ang's injunction to transform the styles of past models creatively. At court, Wang Yüan-ch'i rose to high office under the K'ang-hsi Emperor and served as chief compiler of the Imperial painting and calligraphy catalog, the *P'ei-wen-chai shu-hua-p'u*.

The "Individualists"

Receiving no patronage from the Manchu court and leaving only a minor following before the latter half of the 19th century was a different group of artists, now frequently referred to as "Individualists." Collectively, these artists represent a triumphant, if short-lived, moment in the history of literati painting, triggered in good part by the emotionally cathartic conquest of China by the Manchus. They shared in common a rejection of Manchu political authority and the choice of an eremitic, often impoverished lifestyle that obliged them to trade their works for their sustenance in spite of their allegiance to amateur ideals. Stylistically, just like their more orthodox contemporaries, they often revealed the influence of Tung Ch'i-ch'ang's systematization of painting method; but, unlike the more conservative masters, they pursued an emotional appeal reflective of their own temperaments. For example, Kung Hsien, a Nanking artist whose budding political career was cut short by the Manchu conquest, used repetitive forms and strong tonal contrasts to convey a pervasive feeling of repressive constraint, lonely isolation, and gloom in his landscapes. He was the most prominent of the artists who came to be known as the "Eight Masters of Nanking." This group was only loosely related stylistically, though contemporary painters from Nanking did share solidity of form derived from Sung prototypes and, possibly, from the influence of Western art.

The landscapes of K'un-ts'an (or Shih-ch'i), who became a somewhat misanthropic abbot at a Buddhist monastery near Nanking, also express a feeling of melancholy. His works were typically inspired by the densely tangled brushwork of Wang Meng of the Yüan.

Another Individualist artist to join the Buddhist ranks was Hung-jen, exemplar of a style that arose in the Hsin-an or Huichou district of southeastern Anhwei province and drew on the famed landscape of the nearby Huang Mountains. The group of artists now known as the "Anhwei School" (including Ting Yün-p'eng, Hsiao Yün-ts'ung, Mei Ch'ing, Cha Shih-piao, and Tai Pen-hsiao) mostly pursued an opposite emotional extreme from Kung Hsien and K'un-ts'an, a severe coolness based on the sparse, dry linear style of the Yüan artist Ni Tsan. However individualistic, virtually all these artists reveal the influence of Tung Ch'i-ch'ang's compositional means.

Two artists, both members of the deposed and decimated Ming royal family, stood out among these Individualist masters and left, albeit belatedly recognized, the most enduring legacy of all. Known by a sequence of names,

The painters Chu Ta and Tao-chi

perhaps designed to protect his royal identity, Chu Ta, or Pa-ta Shan-jen, suffered or at least feigned a period of madness and muteness in the 1680s. He emerged from this with an eccentric style remarkable for its facility with extremes, alternating between a wet and wild manner and a dry, withdrawn use of brush and ink. His paintings of glowering birds and fish casting strange and ironic glances, as well as his structurally interwoven studies of rocks and vegetation, are virtually without precedent in composition, although aspects of both the eccentric Hsü Wei and Tung Ch'i-ch'ang are discernible in his work. His esoteric inscriptions reveal a controlled intent rather than sheer lunacy and suggest a knowledgeable, if hard to unravel, commentary on China's contemporary predicament.

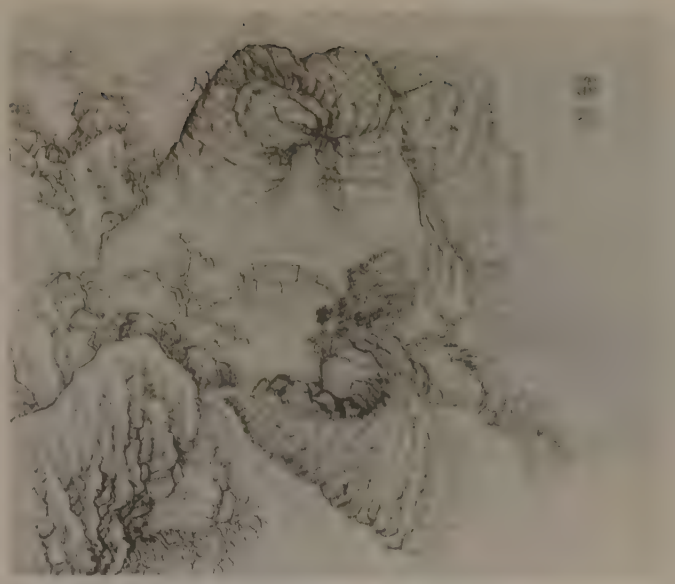
Chu Ta's cousin Tao-chi was raised in secret in a Ch'an Buddhist community. He traveled widely as an adult in such varied artistic regions as the Huang Mountains district of Anhwei province and Nanking and finally settled in the newly prosperous city of Yang-chou, where in his later years he publicly acknowledged his royal identity, renounced his Buddhist status, and engaged in professional practices. His work has a freshness inspired not by masters of the past but by an unfettered imagination, with brush techniques that were free and unconventional and a daring use of colour. In his essay *Hua yü lu* ("Comments on Painting"), he ridiculed traditionalism, writing that his own method was "no method" and insisting that, like nature, creativity with the brush must be spontaneous and seamless, based on the concept of *i-hua*, the "unifying line."

Tao-chi's extreme stand in favour of artistic individuality stands out against the growing scholasticism of Ch'ing painting and was an inspiration to the artists, roughly grouped together as the "Eight Eccentrics" (including Cheng Hsieh, Hua Yen, Huang Shen, Kao Feng-han, Chin Nung, and Lo P'ing), who were patronized by the rich merchants in early 18th-century Yang-chou. The art of Chu Ta and Tao-chi was not firmly enshrined, however, until the late 19th century, when a new individualist thrust appeared in Shanghai in response to the challenge of Western culture. Their influence on Chinese art since then, especially in the 20th century, has been profound.

Calligraphy. Those who straddled the Ming-Ch'ing transition continued the exploration of individualistic calligraphic styles (particularly in cursive and semicursive scripts) and included many who also excelled at painting, such as Fu Shan, Fa Jo-chen, Chu Ta, and Tao-chi. The chief contribution of Ch'ing calligraphers came later, however, with a resurgence in the importance of seal and clerical scripts (which had survived primarily in seal carving and in the writing of titled frontispieces for painted hand scrolls). This was based on a renewed scholarly interest in inscribed Chou dynasty bronzes and in northern stelae of the Han, Six Dynasties, and T'ang periods. While an indication of Chinese calligraphers' interest in seal and clerical type scripts can already be seen in the early Ch'ing writings of Fu Shan, Chu Ta, and Tao-chi, a more scientific study of bronze and stone inscriptions (*chin-shih hsüeh*) was begun in the early to mid-18th century by such scholar-calligraphers as Wang Shu. Thereafter, practitioners could be divided among imitative calligraphers and those who were more creative in their adaptation of these ancient scripts. Among the latter were the 18th-century Yang-chou painters Chin Nung and Kao Feng-han, as well as the 18th- and 19th-century calligraphers Teng Shih-ju, I Ping-shou, Juan Yüan, and Wu Ta-ch'eng. The interest in ancient styles continued in the early 20th century, when the paleographer Tung Tso-pin and other calligraphers pioneered the adaptation to the modern brush of the script used to inscribe Shang dynasty divinations, which had recently been excavated.

Ceramics. The pottery industry suffered severely in the chaotic middle decades of the 17th century, of which the typical products are "transitional wares," chiefly blue-and-white. The Imperial kilns at Ching-te-chen were destroyed and were not fully reestablished until 1682, when the K'ang-hsi Emperor appointed Ts'ang Ying-hsüan as director. Under his control, Imperial porcelain reached a level of excellence it had not seen for well over a century.

Imperial porcelain



"Hut at the Foot of Mountains," album leaf by Tao-chi, *c.* 1695, Ch'ing dynasty. Ink and colour on paper. In the C.C. Wang Family Collection, New York City. 24.1 × 27.9 cm.
From the C C Wang Family Collection, New York City

The finest pieces include small monochromes, which recaptured the perfection of form and glaze of classic Sung wares. New colours and glaze effects were introduced, such as eel-skin yellow, snakeskin green, turquoise blue, and an exquisite soft red glaze shading to green (known as "peach-bloom") that was used for small vessels made for the scholar's desk. Also perfected was *lang-yao* (sang-de-boeuf, or oxblood, ware), which was covered with a rich copper-red glaze. K'ang-hsi period blue-and-white is particularly noted for a new precision in the drawing and the use of cobalt washes of vivid intensity.

Five-colour (*wu ts'ai*) overglaze painted wares of the K'ang-hsi period became known in Europe as famille verte from the predominant green colour in their floral decoration. These wares also included expert imitations of overglaze painting of the Ch'eng-hua Emperor's reign. Another variety has floral decoration painted directly on the biscuit (unglazed pottery body) against a rich black background (famille noire). Toward the end of the K'ang-hsi reign, a rose pink made from gold chloride was introduced from Europe. It was used with other colours in the decoration of porcelain (famille rose) and in cloisonné and overglaze painting.

Famille rose porcelain reached a climax of perfection at Ching-te-chen under the direction of Nien Hsi-yao (1726–36) and continued with scarcely diminishing delicacy through the Ch'ien-lung period. Meanwhile, the skill of the Ching-te-chen potters was being increasingly challenged by the demand at court for imitations in porcelain of archaic bronzes, gold, and jade and for such inappropriate objects as musical instruments and perforated and revolving boxes, which were highly unsuited to manufacture in porcelain. Although fine porcelain was made from time to time in the 19th century, notably in the Tao-kuang and Kuang-hsü reigns, the quality as a whole greatly declined.

Textiles. Ming and Ch'ing textiles fully display the Chinese love of pageantry, colour, and fine craftsmanship. Prominent among woven textile patterns are flowers and dragons against a background of geometric motifs that date to the late Chou and Han. Ch'ing robes were basically of three types. The *ch'ao-fu* was a very elaborate court ceremonial dress; the emperor's robe was adorned with the auspicious Twelve Symbols described in ancient ritual texts, while princes and high officials were allowed nine symbols or fewer according to rank. The *ts'ai-fu* ("coloured dress"), or "dragon robe," was a semiformal court dress in which the dominant element was the Imperial five-clawed dragon (*lung*) or the four-clawed dragon (*mang*). In spite of repeated sumptuary laws issued during the Ming and Ch'ing, the five-clawed dragon was seldom reserved for

Three types of Ch'ing robe

objects of exclusively Imperial use. Symbols used on the dragon robes also included the eight Buddhist symbols, symbols of the Taoist Eight Immortals, eight precious things, and other auspicious devices. "Mandarin squares" had been attached front and back to Ming official robes as symbols of civil and military rank and were adapted by the Manchus to their own distinctive dress.

Jade and small-scale carving. China directly controlled the Central Asian jade-yielding regions of Ho-tien and Yarkand between about 1760 and 1820, during which time much fine nephrite was sent to Peking for carving. Jadeite from Myanmar (Burma) reached the capital from the second quarter of the 18th century, and chromite- or graphite-flecked "spinach jade" from the Baikal region of Siberia was imported in the 19th century. The finest Ch'ing dynasty jade carving is often assigned to the reign of Ch'ien-lung, but carved jade is difficult to date. Typical of what is considered of Ch'ien-lung date are vases with lids and chains carved from a single block, vessels in antique bronze shapes with pseudo-archaic decoration, fairy mountains, and brush pots for the scholar's desk.

The same forms and motifs were also skillfully employed in the carving of other ornamental minerals, such as rock crystal, rose quartz, agate, lapis lazuli, and soapstone. Owing to the early perfecting of porcelain in China, glassmaking never became a major craft. In the 18th century, however, it was somewhat developed, partly under Western influence, the chief centre of production for the court being Po-shan in Shantung. Other minor crafts that achieved a high level of technical virtuosity in the Ch'ing dynasty include the carving of birch root, bamboo root, rhinoceros horn, elephant ivory, and hornbill ivory. Snuff bottles were made from a variety of hard stones, porcelain, glass, coral, cloisonné, and other materials. The technique of painting on the inside of glass snuff bottles was developed in the second half of the 19th century.

Other minor crafts

Modern period (since 1912). The arts of China since 1912 have reflected the emergence of China into the modern world, the impact of Western art, and the political and military struggles of the period, culminating in the war with Japan (1937–45) and the civil war that ended in the establishment in 1949 of the People's Republic of China.

Architecture. Until the mid-1920s official and commercial architecture were chiefly in the eclectic European style of such treaty ports as Canton, Amoy, Fu-chou, and Shanghai, much of it designed by foreign architects. In 1925, however, a group of foreign-trained Chinese architects launched a renaissance movement to study and revive traditional Chinese architecture and to find ways of adapting it to modern needs and techniques. In 1930 they founded Chung-kuo Ying-tsao Hsüeh-she, the Society for the Study of Chinese Architecture, which was joined in the following year by Liang Ssu-ch'eng, the dominant figure in the movement for the next 30 years. The fruits of their work can be seen in new universities and in major government and municipal buildings in Nanking and Shanghai. The war with Japan put an end to further developments along these lines, however. Since 1949, Peking and other big cities have been transformed by spectacular planning projects, but an awareness of the traditional role of symbolism in architecture has been retained and adapted to communist propaganda purposes. Large portions of the Forbidden City in Peking have been restored and established as a public museum, but a section has been given over to residences for the new ruling elite. A new primary thoroughfare (Ch'ang-an Boulevard) has been established, running east and west in front of the old palaces, contrary to the old north-south axis. A vast square for public political activity has been created in front of the Gate of Heavenly Peace (T'ien-an Men, entryway to the Imperial City), flanked on one side by the Museum of Chinese History and the Revolution and on the other by the Great Hall of the People, built in Soviet style in 1959 during the Great Leap Forward. Most of the city's magnificent walls were torn down before or during the Cultural Revolution on the pretext that they impeded the flow of traffic. Finally, the regime's founder, Mao Zedong, who died in 1976, was buried in a mausoleum bearing a striking resemblance to the Lincoln Memorial in Washington, D.C.; the tomb is located in the centre of the city at the south end of Tien-anmen Square, where it obstructs the north-south axis in flagrant violation of traditional geomantic principles.

Urban planning projects

Painting and printmaking. Shanghai, which had been forcibly opened to the West in 1842 and boasted a newly wealthy clientele, was the logical site for the first modernist innovations. A Shanghai regional style appeared by the 1850s, led by Jen Hsiung, his more popular follower Jen I (or Jen Po-nien), and Jen I's follower Wu Ch'ang-shih. It drew its inspiration from a series of Individualist artists of the Ming and Ch'ing, including Hsü Wei, Ch'en Shun, Ch'en Hung-shou, Chu Ta, and Tao-chi; it focused on birds and flowers and figural themes more than the old landscape tradition; and it emphasized decorative qualities, exaggerated stylization, and satiric humour rather than refined brushwork and sober classicism. Under Wu Ch'ang-shih's influence, this style was passed on to Peking through the art of Ch'en Heng-k'o (or Ch'en Shih-tseng) and Ch'i Pai-shih in the first years after the revolution.

The Japanese faced the issues of modernization earlier than the Chinese, blending native and Western traditions in Nihonga painting and establishing an institutional basis of support under the leadership of Okakura Kakuzō, who founded the Tokyo Fine Arts School in 1889. Thus, it is not surprising that among the first in China to respond similarly were artists who had traveled to Japan, including Kao Chien-fu, his brother Kao Ch'i-feng, and Ch'en Shu-jen. Inspired by the "New Japanese Style," the Kao brothers and Ch'en inaugurated a "New National Painting" movement, which in turn gave rise to a Cantonese (or "Ling-nan") regional style that incorporated Euro-Japanese characteristics. Although the new style did not produce satisfying or lasting solutions, it was a significant harbinger and continued to thrive in Hong Kong, practiced by such artists as Chao Shao-ang. The first establishment of Western-style art instruction also dates from this period. A small art department was opened in Nanking High Normal School in 1906, and the first art academy, later to become the Shanghai Art School, was founded in the year of the revolution, 1911, by the 16-year-old Liu Hai-su, who in the next decade pioneered the first public exhibitions (1913) and the use of live models, first clothed and then nude, in the classroom.

Establishment of Western-style art schools

Increasingly, by the mid-1920s, young Chinese artists were attracted not just to Japan but also to Paris and German art centres. A trio of these artists brought back some understanding of the essential contemporary European traditions and movements. Liu Hai-su was first attracted to Impressionist art, while Lin Feng-mien, who became director of the National Academy of Art in Hang-chou in 1928, was inspired by Postimpressionist experiments in colour and pattern by Henri Matisse and the Fauvists. Lin advocated a synthesis combining Western techniques and Chinese expressiveness and left a lasting mark on the modern Chinese use of the brush. Hsü Pei-hung, head of the National Central University art department in Nanking, eschewed European modernist movements in favour of Parisian academism. He developed his facility in drawing and oils, later learning to imitate pencil and chalk with the Chinese brush; the monumental figure paintings he created served as a basis for Socialist Realist painters after the communist revolution of 1949. By the 1930s, all these modern trends were clearly developed and institutionalized. Although most of the major artists of the time advocated modernism, two continued to support more traditional styles: Ch'i Pai-shih, who combined Shanghai style with an infusion of folk-derived vitality, and the relatively conservative landscapist Huang Pin-hung, who demonstrated that the old tradition could still produce a rival to the great masters of the 17th century.

Socialism produced a new set of artistic demands that were first met not by painting but by the inexpensive mass medium of woodblock prints (which had been invented in China and first used in the T'ang dynasty to illustrate Buddhist sutras). Initially stimulated by the satiric leftist writer Lu Hsün, printmakers flourished during the 1930s and '40s under the dual influence of European socialist artists like Käthe Kollwitz and the Chinese folk tradition of New Year's prints and papercuts. Among the most

prominent print artists were Li Hua and Ku Yüan, who attained a new standard of political realism in Chinese art.

Aesthetic principles of the Communist Party

In 1942, as part of the Chinese Communist Party's first intellectual rectification movement, Mao Zedong delivered two speeches at the Yen-an Forum on Literature and Art that became the official party dictates on aesthetics for decades to come. Mao emphasized the subordination of art to political ends, the necessity for popularization of styles and subjects in order to reach a mass audience, the need for artists to share in the lives of ordinary people, and the requirement that the party and its goals be treated positively rather than subjected to satiric criticism. "Art for art's sake" was strictly denounced as a bourgeois liberal attempt to escape from the truly political nature of art. Although Mao later defended a place for the artistic study of nude models, a staple of Western naturalism, the tone he set led to severe limitations in the actual practice of this.

The Sino-Japanese War of 1937–45 led many artists of varied persuasions to flee eastern China for the temporary Nationalist capital in Chungking, Szechwan province, bringing a tremendous mixing of styles and artistic ferment, but the opportunity for innovation which this promised was thwarted by subsequent events. After the 1949 revolution, Communist Party control of the arts was firmly established by the placement of the academies under the jurisdiction of the Ministry of Culture, by the creation of artists' federations and associations (which served as an exclusive pathway to participation in exhibitions and other means of advancement) under the management of the party's Department of Propaganda, by the establishment of a strict system of control over publications, and by the virtual elimination of the commercial market for contemporary arts.

Throughout the 1950s, as Socialist Realist standards were gradually implemented, oil painting and woodblock printing were favoured and political cartoons and posters were raised to artistic status. Artists in the traditional media—with their basis in the Individualist art of the old "feudal" aristocracy—struggled institutionally for survival, eventually succeeding only as a result of the nationalist fervour that accompanied China's ideological break with the Soviet Union late in the decade. The internationalist but relatively conservative Hsü Pei-hung was installed as head of the new Central Academy of Fine Arts in Peking but died in 1953. Other older-generation leaders passed on shortly afterward (Ch'i Pai-shih and Huang Pin-hung) or were shunted aside (Liu Hai-su and Lin Feng-mien), and a younger generation soon came to the fore, ready to make the necessary compromises with the new regime. The talented landscapist Li Keran, who had studied with Ch'i Pai-shih, Lin Feng-mien, Huang Pin-hung, and Hsü Pei-hung, combined their influences with realistic sketching to achieve a new naturalism in the traditional medium. A leading figure painter was Cheng Shifa, a descendant of the Shanghai school who brought that style to bear in politically polished depictions of China's minority peoples. Many talented artists, including Luo Gongliu and Ai Zhongxin, painted in oils, which, because of their link to the Soviet Union and Soviet art advisors, held a favoured position until the Sino-Soviet split of the late 1950s.

The Cultural Revolution

While the early 1960s provided a moment of political relaxation for Chinese artists, the Cultural Revolution of 1966–76 brought unprecedented hardships, ranging from forced labour and severe confinement to death. Destruction of traditional arts was especially rampant in the early years of the movement. Only those arts approved by a military-run apparatus under the sway of Mao's wife, Jiang Qing, could thrive; these followed the party's increasingly strict propagandist dictates and were often created anonymously as collective works.

The passing of Mao and Maoism after 1976 brought a new and sometimes refreshing chapter in the arts under the leadership of Deng Xiaoping. The 1980s were characterized by decreasing government control of the arts and increasingly bold artistic experimentation. Three phenomena in 1979 announced this new era: the appearance of Cubist and other Western styles, as well as nude figures, in the murals publicly commissioned for the new Peking airport (although the government "temporarily" covered the nudes); a private arts exhibition by The Stars art group at the Peking Art Gallery; and the rise of a truly realistic oil painting movement, which swept away the artificiality of Socialist Realist propaganda. A resurgence of traditional Chinese painting occurred in the 1980s, featuring the return of formerly disgraced artists, including Li Keran, Cheng Shifa, Shi Lu, and Huang Yongyu, and the emergence of such fresh talents as Wu Guanzhong, Jia Youfu in Sian, and Li Huasheng of Szechwan province.

"Fleeing Refugees," woodblock print by Li Hua, 1944. Ink on paper. 21 × 4.6 cm.

After 1985, as an increasingly bold avant-garde movement arose, the once-threatening traditional-style painting came to seem to the government like a safe alternative. In the final months before the June 1989 imposition of martial law in Peking, an exhibition of nude oil paintings from the Central Academy of Fine Arts at the Chinese National Gallery and an avant-garde exhibition featuring installation art, performance art (which lacked the necessary permit for a public gathering), and the mockery of the government through printed scrolls full of unreadable pseudo-characters drew record crowds. The latter was closed by police, and both exhibits were eventually denounced as having lowered local morals, helping to precipitate the tragic events that followed in June 1989. New limitations on artistic production, exhibition, and publication ensued. At the conclusion of these events, a number of leading artists, including Huang Yongyu, fled China, joining others who had previously fled or abandoned China to establish centres of Chinese art throughout the world. Among the leading Chinese artists outside mainland China have been Chao Wu-chi (Zao Wou-ki), who settled in Paris; Chang Dai-chien in Taiwan, Brazil, and the United States; Wang Chi-ch'ien (C.C. Wang) and Tseng Yu-ho in the United States; Liu Kuo-sung, Ch'en Ch'i-kwan, and Ho Huai-shuo in Taiwan; Fang Chao-lin in Hong Kong and London; and Lin Feng-mien in Hong Kong. (M.Su./Je.Si.)

Korean visual arts

GENERAL CHARACTERISTICS

The art produced by peoples living in the peninsula of Korea has traditionally shared aesthetic concepts, motifs, techniques, and forms with the art of China and Japan. Yet it has developed a distinctive style of its own. In general, Korean art has neither the grandeur and aloofness of Chinese art nor the decorative sophistication of Japanese art, and Korean artists were often not as technically perfect or precise as their Chinese and Japanese counterparts. Instead, the beauty of Korean art and the strength of its artists lay in simplicity, spontaneity, and a feeling of harmony with nature. In mood, the art of Korea is often characterized by a sense of loneliness arising from the serenity of the image and reflecting the Korean philosophy of resignation.

The basic trend of Korean art has been naturalistic, a

characteristic already evident as early as the Three Kingdoms period (*c.* 57 BC–AD 668) but fully established by the Unified, or Great, Silla (Korean: Shinla) period (668–935). The traditional attitude of accepting nature as it is resulted in a highly developed appreciation for the simple and unadorned. Korean artists, for example, favour the unadorned beauty of raw materials, such as the natural patterns of wood grains. The Korean potter was characteristically unconcerned about mechanical perfection of his surfaces, curves, or shapes. His concern was to bring out the inherent or natural characteristics of his materials and the medium. Potters, therefore, were able to work unself-consciously and naturally, producing wares of engaging simplicity and artistic distinctiveness.

Simplicity applied not only to economy of shape but also to the use of decorative motifs and devices. The intervention of the human hand is restricted to a minimum in Korean art. A single stem of a flower, for instance, may be drawn in a subtle shade of blue on the side of a white porcelain vase or bottle, but never merely from a desire to fill an empty space. The effect is rather to enlarge the white background.

The avoidance of extremes is another characteristic tradition in Korean art. Extreme straightness of line was disliked as much as extreme curvilinearism. The straight bold contour of a Sung dynasty (960–1279) Chinese bowl becomes a graceful, modest curve in a Korean bowl of the Koryŏ period (918–1392). The sharply curving Chinese roof is modified into a gently sloping roof. Sharp angles, strong lines, steep planes, and garish colours are all avoided. The overall effect of a piece of Korean art is generally gentle and mellow. It is an art of fluent lines. What is most striking is not the rhythm so much as the quiet inner harmony.

STYLISTIC AND HISTORICAL DEVELOPMENT

The formative period. Both archaeological and linguistic evidence indicates that the Korean people originally spread into the Korean peninsula from Siberia by way of Manchuria. Prehistoric sites dating from the Paleolithic and Neolithic periods are found throughout the peninsula.

Sporadic Chinese influence on Korean culture began in the late Neolithic Period, but the influence intensified with the establishment in 108 BC of colonies of the Han empire in northwestern Korea. The best known of these was Nangnang (Chinese: Lo-lang), near P'yŏngyang. From this Chinese centre of culture, iron smelting and advanced techniques of pottery making, such as the use of a potter's wheel and closed kiln, spread across the peninsula.

Comb-pattern pottery

The earliest Neolithic potteries, produced in the 6th millennium BC, are flat-bottomed wares decorated with raised horizontal lines, a zigzag pattern around the rim, or horizontal rows of impressed dots or fingernail marks. In the 5th millennium BC the latter type evolved into what is known as comb-pattern pottery, which characteristically features a pointed or rounded bottom and overall geometric patterns of herringbone, meander, and concentric semicircles, produced by incised, impressed, or dragged dots and short lines. The linear, abstract tendency of these Neolithic potteries basically falls in the tradition of prehistoric Siberian art.

Kyŏngee University Museum, Seoul

Neolithic comb-pattern pottery, from Amsadong, Seoul, *c.* 4th millenium BC. In the Kyŏnghee University Museum, Seoul. Height 40.5 cm.

In the ensuing Bronze Age (*c.* 1000–300 BC) and Early Iron Age (*c.* 300–0 BC) more types of pottery of improved quality appeared. Painted pieces derived from Chinese painted pottery have been found in North Korea, while wares devoid of surface decoration were used in other areas of the peninsula. Clay, bone, or stone figurines of seated or standing shamanistic deities were also produced.

It was also during this time that bronze- and iron-working centres were established in Korea. Bronze daggers, mirrors, and perforated pole finials, all ultimately of Siberian origin, were cast. The daggers are of the type widely used by the Scythian peoples of the Eurasian steppe. The mirrors were also of a non-Chinese type, with twin knobs placed a little off centre against a tightly composed, geometric design made up of finely hatched triangles.

More evidence of the Siberian art tradition in prehistoric Korea can be seen in a rock-cut drawing discovered in 1970 at Pan'gudae, near the southeastern coast of South Korea. Pecked line drawings and silhouettes of animals, including whales, dolphins, tigers, wolves, and deer, are depicted on a large (8 by 2 metres), smooth vertical surface of the rock. Some of the animals have a "life line" drawn from the mouth to the anus in the so-called X-ray style of Siberian rock art.

Three Kingdoms period (*c.* 57 BC–AD 668). The first major period of Korean art during recorded history is the period of the Three Kingdoms (*c.* 57 BC–AD 668), when the peninsula of Korea was ruled by three monarchies. The Koguryŏ kingdom (traditionally dated 37 BC–AD 668) was the northernmost of the three, both geographically and culturally. First established in southern Manchuria, its lifestyle was based on the typically austere cultural patterns of northern Asia, evolved in a region characterized by its scarcity of arable land and severity of climate. The Paekche kingdom (traditionally dated 18 BC–AD 660) was centred in southwestern Korea, south of the present-day city of Seoul. This was a favourable geographic position for receiving foreign cultural influences. Paekche art, therefore, was open and receptive to Chinese influences. Northern Chinese cultural elements were introduced by land through the Koguryŏ kingdom, while southern Chinese influences easily crossed the navigable East Asian seas. The kingdom of Silla (traditionally dated 57 BC–AD 668) was the oldest of the monarchies. It originated in the present city of Kyŏngju and eventually came to cover most of southeastern Korea east of the Naktong River. The original territory of the Silla kingdom, the modern North Kyŏngsang province, is a mountain-secluded triangle, a geographic factor sometimes offered as an explanation for the distinctiveness and conservatism of its art.

The kingdoms of Koguryŏ, Paekche, and Silla

The introduction of Buddhism into Koguryŏ from China (AD 372) brought a sudden efflorescence of the arts. Until that time a sustained tradition of large-scale art had been virtually nonexistent. The Koguryŏ kings started the building of temples and pagodas, and sculpture, in the form of Buddha images, made its appearance. By the 6th century, the Silla and Paekche kings had also become converts to the new faith, and from then on Buddhism remained the main inspiration of Korean art until the 15th century.

During the Three Kingdoms period there were three political and cultural centres: P'yŏngyang, the capital of Koguryŏ, in the northwest; the Kongju-Puyŏ region, the Paekche heartland, in the southwest; and Kyŏngju, the capital of Silla, in the southeast. Silla and Paekche, along with the minor state of Kaya (also known as Kara or Karak; Japanese: Mimana) in the south, maintained close cultural contacts with Japan, and it was at this time that the significant Korean influence on Japanese art began. The Paekche kingdom first introduced Buddhism and Chinese writing to Japan. South Korean immigrants to Japan founded important centres of learning and the arts. The Sue pottery of the Tumulus, or Kofun, period (also

known as the Great Burial Period) was the Japanese version of the Silla pottery of Korea. Even the famed wall paintings of the Hōryū Temple in Nara, Japan, have been attributed to a northern Korean painter, Tamjing, from the Koguryŏ kingdom.

Except for several small Buddhist images in bronze and clay, very little remains of Koguryŏ's religious art. A considerable amount, however, has been preserved from the two southern kingdoms. Paekche was the first to use granite in the construction of pagodas and sculpture. After the Three Kingdoms period, granite, which is abundant in Korea, was widely used in construction and sculpture. The granite pagodas of Korea stand in sharp contrast to the brick pagodas of China and the wooden pagodas of Japan.

Earliest uses of granite

The surviving secular art of the period consists chiefly of burial gifts taken from tombs. Not much is available from Koguryŏ and Paekche, because the tombs were too easily accessible and have long since been looted. However, much pottery, along with items used for personal adornment, has continued to turn up in the second half of the 20th century from the less accessible Silla tombs. The most valuable pieces of Old Silla art came from huge mounded tombs in the Kyŏngju area. The rich Silla gold mines, exhaustively worked, yielded the abundance of gold ornaments reflected in the ancient Japanese epithet Manokagayaku Shiragi, or "Eye-Brightening Silla."

Architecture. No original examples of Koguryŏ architecture remain, except for some foundation stones that vaguely suggest a building site, possibly of a royal villa, on the Yalu River near Chi-an, China. In the P'yŏngyang area, three temple sites, probably of the late 5th or early 6th century, have been discovered. These were situated on low terraces, and in each case the central structure was an octagonal wooden pagoda with sides 10 metres long. The pagoda was probably a tall, multistoried structure in the style of the Yingning Temple pagoda built in Lo-yang, China, in AD 467. Facing the central pagoda on three sides (north, east, and west) were Buddha chapels. This arrangement, one pagoda with three surrounding halls, seems to have been the earliest Buddhist temple plan used. The very same plan can be seen at a Paekche temple site in Puyŏ and at the site of the Asuka-dera temple near Kyōto, Japan. The Paekche temple also had a central octagonal wooden pagoda. In Silla, however, as can be seen in the well-known Hwang'yong Temple of Kyŏngju, the Koguryŏ-Paekche plan was modified to a one-pagoda (south), one-chapel (north) system.

Though the wooden structures of the period have been completely destroyed, three stone pagodas still exist, two in the Paekche area and one in Kyŏngju. At first Koreans built replicas of Chinese multistory wooden pagodas; but, since wooden structures were expensive and difficult to maintain, the idea arose, first in Paekche, of using stone. Paekche architects initially tried to copy the wooden pagoda as faithfully as possible. A good example of this is the stone pagoda at the Mirŭk Temple south of Puyŏ. Later, however, pagodas became smaller, and architectural details were much simplified, as can be seen in the five-story pagoda in Puyŏ. The square pagoda stands on the elevated platform of granite, and each story is capped by a thin roofstone with projecting eaves. The stories diminish progressively in size as they go upward, forming a characteristic slender and stabilized type from which the later Silla pagodas evolved. The only remaining Silla pagoda is at the Punhwang Temple in Kyŏngju, constructed in 634, a stone version of a Chinese brick pagoda of the T'ang dynasty (618–907).

Painting. Paintings from the Three Kingdoms are mainly those from decorated tombs. The earliest dated Koguryŏ tomb, the Tomb of Tongsu, or Tomb No. 3, in 'Anak, south of P'yŏngyang, was built in 357. All other known tombs except for Tokhŭng-ni Tomb, bearing an inscription datable to 408 AD, are undated but can be roughly classified as early (4th century), middle (5th century), or late (6th century). The early tomb murals were portraits of the dead master and his wife, painted either on the nichelike side walls of an entrance chamber or on the back wall of the main burial chamber. The paintings were executed in fresco, a technique of painting with water-soluble pigments on plaster. The colours used were black, deep yellow, brownish red, green, and purple. The general tone of the paintings is subdued and often gives a strange melancholic impression. In the middle stage, though portraits were still painted, they depicted the dead master in connection with some important event in his life, rather than seated solemnly and godlike as in the earlier period. In the Tomb of the Dancing Figures in the T'ung-kou region around Chi-an, the master is shown on the northern wall of the main chamber feasting with visiting Buddhist monks. A troupe of dancers is painted on the eastern wall and a hunting scene on the western one. The delicate wiry outlines of the first phase of Korean mural painting are replaced by bold, animated lines, which are quite distinct from the prevailing Chinese styles. In the hunting scene, mounted warriors shoot at fleeing tigers and deer. Lumps of striated clay are used to depict mountain ranges. Forceful brushstrokes are used to heighten the effect of motion of the galloping horses and fleeing game. This naive sense of dynamism is characteristic of Koguryŏ painting.

Tombs decorated with frescoes

In the third and final stage of Koguryŏ mural art, the technique of fresco painting was improved and imagery refined. Lines flow and colours are intensified. Genre paintings of preceding stages disappeared and the Four Deities of the cardinal compass points now occupied the four walls in Chinese fashion, a concept derived from Taoist religious art of the T'ang period. Dating probably from the first half of the 7th century, the paintings of the Three Tombs at Uhyŏn-ni, near P'yŏngyang, and of the Tomb of the Four Deities in Chi-an are the best examples from the final phase of Koguryŏ fresco painting.

Tomb painting spread to Paekche, where two examples of tomb wall painting can be found, the tombs of Songsan-ni in Kongju and of Nŭngsan-ni in Puyŏ. In addition, a pillow from the tomb of King Muryŏng (501–523), in Kongju, features fish and dragons and lotus flowers painted in flowing exquisite lines in ink against a red background. In the greater Silla area, one decorated tomb at Koryŏng in the former Kaya territory and two tombs discovered in the 1980s at Yŏngju have survived, but the paintings in all three are badly damaged. The best example of painting from the Old Silla period is found on a saddle mudguard made of multi-ply birch bark discovered in the Tomb of the Heavenly Horse in Kyŏngju in 1973; the mudguard depicts a galloping white horse surrounded by a band of floral design.

Beginnings of Buddhist sculpture

Sculpture. Buddhist sculpture probably began in the Koguryŏ kingdom in the 5th century. No 5th-century pieces survive, however, except for some fragments of terra-cotta figures. The earliest dated Koguryŏ Buddhist image is a gilt-bronze standing Buddha. It has an inscribed date that may correspond to the year 539. The elongated face, the flared drapery, and the mandorla or almond-shaped aureole, decorated with a flame pattern, all point to the influence of Chinese sculpture of the Northern Wei period (386–534.) A close adherence to the stylized linear tradition of northern Chinese sculpture was, in fact, the main characteristic of Koguryŏ sculpture.

In Paekche the Koguryŏ-type Buddha became more naturalistic and thus more Korean in style. The Buddha's face is rounder and more expressive, with the distinctive "Paekche smile." The style was apparently influenced by the softly modeled sculpture of southern China, particularly of the Southern Liang dynasty (502–557), when many Chinese artisans are believed to have come to Paekche. The best piece among some 18 or so extant Paekche gilt-bronze Buddhist images is a standing bodhisattva, or figure of one who has attained enlightenment. Now in the Ichida collection in Japan, it was originally from a temple site in Puyŏ. The seated Maitreya, or image of the future Buddha dwelling in the Tuṣita heaven (National Museum of Korea, Seoul), is of unknown provenance, although the round face, the well-proportioned feminine body, and the animated, naturalistic drapery suggest Paekche workmanship of about 600. The pinewood bodhisattva in the Kōryū Temple, Kyōto, Japan, has the same facial expression and posture, and it is believed to be the Maitreya sent from Korea in 623, as is recorded in *Nihon shoki*, the official history of Japan compiled in the 8th century. To-

ward the end of the Paekche dynasty, rock-cut sculpture, in the form of relief figures on exposed outdoor rocks, appeared. Dating from the mid-7th century, the first such example is at Sŏsan in South Ch'ungch'ŏng province. It is a Śākyamuni triad, or the historical Buddha flanked by the bodhisattvas Mañjuśrī and Samantabhadra.

Silla followed the naturalistic Paekche style but in a more static and conservative fashion. The seated gilt-bronze Silla Maitreya in the National Museum of Korea is of the same size as the Paekche Maitreya and is cast in the same pose of a half cross-legged figure in meditation. The drapery, however, is very conventionalized, and the image lacks the animation of the Paekche statue. In the 7th century the creation of stone sculpture increased in the Silla kingdom. Kyŏngju became the centre of production. Much of this stone statuary reflected influences from early T'ang sculpture of the 7th century, particularly in the characteristic interest in the body mass.

Decorative arts. Metalwork was one of the most developed mediums of the decorative arts in the Three Kingdoms period. Kings and high-ranking officials wore gold or gilt-bronze crowns and diadems and also adorned themselves with earrings, necklaces, bracelets, and finger rings made of gold, silver, bronze, jade, and glass. The best surviving pieces of jewelry and regalia come from intact Silla tombs. Only five gold crowns, coming from five Kyŏngju tombs, had been discovered by the early 1990s. The most elaborate, discovered in 1921 in the Tomb of the Golden Crown, consists of an outer circlet with five upright elements and a separate inner cap with a hornlike frontal ornament. It is made of cut sheet gold, and three of the frontal uprights are trees done in a highly stylized manner, flanked by two antler-shaped uprights. Numerous spangles and crescent-shaped pieces of jade (*magatama*) are attached to the vertical elements by means of twisted wire. The worship of trees and antlers was almost universal among ancient peoples of Central and Northern Asia, where the Koreans of the Three Kingdoms originated.

Silla crowns

The most representative type of Three Kingdoms pottery is the hard, grayish, unglazed stoneware of Silla. The predominant type of vessel forms are mounted cups and jars with erect cylindrical necks. At the foot of the cups are four or more rectangular apertures. There are also many human and animal figurines. In Paekche, tiles of gray clay were produced around Puyŏ in the 7th century, many with reliefs of boldly stylized landscapes.

Unified, or Great, Silla period (668–935). In 660 and 668, respectively, the Paekche and Koguryŏ kingdoms fell to the allied armies of the Silla king and the T'ang Chinese emperor, creating a new political and cultural era referred to as the Unified Silla period. This was the golden age of Korean art. Buddhism enjoyed a renewed prosperity, and great temples sprang up one after another in the Kyŏngsang region. Monks and scholars traveled to T'ang China to partake of its brilliant cosmopolitan culture. Korean culture was rapidly Sinicized. The capital city of Kyŏngju (like the contemporary Japanese capital of Heian-kyo, later Kyōto) was modeled after the T'ang capital of Ch'ang-an, with broad, straight avenues laid out on a rectangular grid pattern. From this time on, southern Korea, particularly the southeast, became the centre of Korean artistic development, and northern Korea, where once an aggressive Koguryŏ art had flourished, diminished in importance.

The Unified Silla period produced more granite Buddhist images and pagodas than any other period. Architectural ornamentation, such as roof tiles decorated with floral and animal designs, was of high quality. The bronzesmiths of Unified Silla did excellent work, as exemplified in numerous huge temple bells, *śarīra* boxes (containing sacred ashes of the Śākyamuni Buddha), and Buddhist statues. Toward the end of the reign, bronze seems to have been in short supply, and statues were cast in iron. One Buddhist painting has survived from the Unified Silla period. It depicts a Buddhist sermon held in a temple. Figures and architecture are represented in fine gold lines on blue-brown paper.

Architecture. Many temples were built during the Unified Silla period, and existing ones were enlarged. The low skyline of Kyŏngju must once have been dominated by towering pagodas. The original layout of a Unified Silla temple is best preserved in the Pulguk Temple to the southeast of Kyŏngju. The temple, constructed in the mid-8th century, is situated at the foot of a mountain and is divided into two adjoining complexes. The approach from the south is by a pair of stone staircases. The main complex is the eastern one, with two stone pagodas, one behind the entrance gate and the other in front of the main hall. One pagoda (Sŏkkat'ap) is in the typical square Silla style and represents Śākyamuni, the historical Buddha. The other pagoda (Tabot'ap) is more elaborate and symbolizes the Prabhūtaratna Buddha. The arrangement apparently symbolizes the Buddhist legend that, when Śākyamuni preached the *Avataṃsaka-sūtra,* the pagoda of Prabhūtaratna emerged out of the earth in witness of the greatness and truth of his preaching. A lecture hall once stood behind the main hall. A long, roofed corridor once surrounded the entire eastern complex, linking the main gate, main hall, and the lecture hall. The western complex symbolizes paradise and has a Hall of Paradise at its centre. The present wooden structures of the temple date from the 17th century, but the stoneworks, such as platforms, staircases, and foundation stones, all date from the Unified Silla period.

The Pulguk Temple

A special annex to the Pulguk Temple complex is the artificial cave temple, Sŏkkuram, on the crest of Mount T'oham about 1.6 kilometres away. The cave temple is a domed circular structure built of granite blocks and resembles a tholos, one of the beehive-shaped tombs built by the ancient Mycenaeans in Greece from about 1600 to 1300 BC. A square anteroom houses eight guardian figures in relief. The main chamber is 8 metres high and about 7 metres across. A large seated Śākyamuni (Amitābha, according to some) about 3.5 metres high, carved out of a single block of granite, occupies the centre on an elevated lotus pedestal. On the surrounding wall are 15 slabs in relief depicting 5 bodhisattvas and 10 disciples in attendance. The sculpture of this cave temple is without doubt the finest achievement of Buddhist art in the Orient.

The Paekche type of stone pagoda was adopted in the Unified Silla period, but certain architectural details of the earlier wooden pagoda were ignored and others simplified. The number of stories was reduced to three in most cases, and the main structure stands on a highly elevated, two-tier base. The roof stones have five-stepped corbels, or five projecting blocks supporting a superstructure. In the Śākyamuni pagoda at Pulguk Temple, a good example of the typical Unified Silla pagoda of the 8th century, the ratio of the widths of the stories from the bottom upward is 4:3:2, and the width of the lower base is equated with the height of the main structure above the upper base. This deliberate layout, unique to the Unified Silla period, makes the 8th-century pagoda a well-balanced and beautifully proportioned structure.

The Prabhūtaratna pagoda at Pulguk Temple is an exceptional case that demonstrates the skill of Unified Silla masonry. It is actually an enlarged stone version of an elaborate *śarīra* shrine. The main shrine, surrounded by railings, is supported by a rooflike square slab resting on four pillars with massive brackets, or supporting elements, to carry a projecting weight. The pillars in turn stand on an elevated platform approached by four staircases. On top of the octagonal main shrine is a small, similarly shaped roof adorned with a complex finial, or crowning ornamental architectural detail.

In addition to Buddhist architecture, other forms, including palatial architecture, flourished. Evidence of the magnificence of the Silla palace in Kyŏngju can be seen in the restored Anapchi (Goose and Duck Pond), a man-made pond originally constructed during the reign of King Munmu (661–681). When the pond was dredged in 1976, the original stone-built banks and a complex device for regulating the intake and outflow of water were discovered. Sites of pond-side pavilions as well as huge natural rocks that had been placed on the slopes of islets and on the banks of the pond also were uncovered, revealing the original layout of the 7th-century royal garden.

Sculpture. The sculpture of the Unified Silla period

Naturalistic granite images

was the high point of Korean naturalism and is marked by an abundance of statues in granite. During the first phase of the period, Korean sculpture was under the fresh influence of Chinese sculpture of the early T'ang period. Unified Silla works showed a certain vigour, though they were often stiff and had an imposing body mass. The tortoise base for the monument of King Muyŏl (d. 661) in Kyŏngju and a Śākyamuni triad at Kunwi are good examples of the first phase.

At the outset of the 8th century, however, Unified Silla sculpture freed itself of stiffness and took on a softened naturalistic look. The standing Amitābha and Maitreya (dated 721) from the site of Kamsan Temple may be considered typical examples of the first half of the 8th century and as stylistic stepping stones leading to the fully mature sculptures of the Sŏkkuram cave temple of the mid-8th century. The main Buddha of the cave temple has a massive body and a full, round face. Yet this is no mere hulking physical mass of monumental stone. The tranquil facial expression, the solid massive curves of the upper torso, and the somewhat formalized, simple drapery are skillfully synthesized and radiate the spiritual power and grace of the Buddha. In the case of the bodhisattvas, shapely feminine bodies are superbly reproduced on the rough granite surface; the curves, however, are covered by thin robes, executed in a stylized manner to de-emphasize the physical attractions and enhance the spiritual qualities. These figures may have been inspired by similar T'ang figures, such as those executed in 703 for the Pao-ching Temple in Sian, China. The Sŏkkuram figures, however, lack the secular and erotic character of the T'ang sculptures.

Saehan International

Monument at the tomb of King Muyŏl, 661, Silla period. In Kyŏngju, Kyŏngsang province.

Stylistic and technical degeneration, however, had already begun in the second half of the 8th century, as is indicated by the two seated bronze Buddhas in the Pulguk Temple. They retain the round, fleshy face of the Sŏkkuram Buddha, but their torsos are overly elongated and the drapery somewhat stylized, so that the spiritual quality is diminished. This mannered style of handling the image increases until the end of the century.

In the 9th century the Unified Silla kingdom itself began to decline. Sculptors were constrained to reduce the size of their pieces, both carved and cast. As a result statues were often out of proportion. A large square block representing the head might be placed on top of a small shrunken body with narrow, sloping shoulders. From about the mid-9th century, bronze came to be used only for small statuettes; large images were cast in iron.

Decorative arts. A considerable number of ceramic urns have been discovered, mainly in the vicinity of Kyŏngju. They are covered with stamped floral patterns, and some have a yellowish green lead glaze. The stamping and glazing were new techniques introduced by potters in the 7th

Bronze bell of King Sŏngdŏk, 771, Unified Silla period. In the Kyŏngju National Museum. Height 3.33 m.

Kyongju National Museum

century. Earthenware roof and square floor tiles also were produced. These were decorated with delicately molded lotus and other rich floral designs and were made for Buddhist temples and palace buildings.

Bronze bells

Bronze work was outstanding in this period, especially the large bronze Buddhist bells. Four Unified Silla bells with inscribed dates survive, two of which are in Japan. A Korean bell of this period differs from a Chinese or Japanese example by the hollow cylindrical tube erected on the crown, alongside the traditional arched dragon handle, and in the surface decoration: the upper and the lower rims of the body are each surrounded by an ornamental horizontal band. Silla skill in casting is best seen in the colossal bronze bell of King Sŏngdŏk that was made in 771 for the Pongdŏk Temple and is now in the Kyŏngju National Museum.

Buddhist bronze shrines for *śarīra* were sometimes placed inside stone pagodas. The best example is from the western pagoda of the Kamŭn Temple site. It is a square platform

Śarīra casket of the Kamŭn Temple, Unified Silla period (668–935). In the National Museum, Seoul. Height 15 cm.

on which a miniature glass bottle containing the *śarīra* is placed under a rich canopy supported by four corner poles. The shrine was encased in a square outer box with a pyramidal cover, each panel of the box adorned with a bronze relief figure of one of the Four Guardians.

Koryŏ period (918–1392). In 935 the Unified Silla monarchy was supplanted by the newly risen Koryŏ dynasty (918–1392). Buddhism once again prospered under royal patronage. Koryŏ's close cultural ties with China during the Sung period (960–1279) resulted in direct influences from the advanced Chinese urban culture, and highly refined, Sinicized lifestyles prevailed among the aristocrats, the more important court officials, and the high-ranking Buddhist priests. The peace of the realm, however, was often disrupted by invaders from Manchuria, first Khitan, then Juchen, and finally by the Mongols. In 1232 the Koryŏ court fled to Kanghwa Island off the west coast of Korea, leaving the country to Mongol devastation and control. The art of Koryŏ never again equaled its pre-Mongol achievements.

Few original examples of Koryŏ architecture have survived. Koryŏ stone sculpture and stone pagoda construction were inferior to that of the Unified Silla period. Examples have survived largely because the Buddhist monks buried their images and ceremonial vessels before abandoning the temples to the Mongols. Good bronze temple bells were cast, although they were smaller in size than those produced in the Unified Silla kingdom. Buddhist sutras were painstakingly copied by monks in gold and silver on thick purple paper. Printing and wood-block engraving were innovations that reached a high state of development. A Koryŏ book is comparable in printing technique to the finest Chinese editions of the Sung period. The famous engraved edition of the entire *Tripiṭaka,* a long Buddhist canonical text, was done in Kanghwa Island in the mid-13th century as a commission of the government in exile. More than 80,000 engraved word blocks were used to print this edition. The major artistic achievement of the Koryŏ period was the production of porcelain with a celadon glaze. Sets of celadon ware were customarily buried with the dead, and it is from these tombs that most of the Koryŏ celadon available in the 20th century has come.

Architecture. Traditional Korean architecture must have been similar to T'ang architecture, which is best illustrated by the main hall of Nan-ch'an Temple (782), Shansi, China. The main hall of the Tōshōdai Temple in Kyōto, Japan, also is believed to be a good example of T'ang-style architecture. In Korea the adaptation of the T'ang architecture is called the *chusimp'o* style. It is characterized by the so-called column-head bracketing, or complexes of brackets that project above the heads or capitals of the columns, with or without intercolumnar struts (inclined supports). One of the best examples of *chusimp'o* architecture is the Muryangsujŏn ("Hall of Eternal Life") of Pusŏk Temple. Dating from the 13th century, this is believed to be one of the oldest wooden structures in Korea.

The *chusimp'o* and *tap'o* styles

About 1300 a new architectural style was brought in from Sung China. Called *tap'o* (multi-bracket), it is characterized by intercolumnar bracketing in place of struts. *Tap'o* became the main style during the following Chosŏn dynasty. Built in the *tap'o* manner are the Pokwangjŏn hall of the Simwŏn Temple and the Eungjinjŏn hall of the Sŏkwang Temple, both of which are datable to the second half of the 14th century. The new *tap'o* buildings are much more decorative than those in the *chusimp'o* style because the intercolumnar brackets fill up the otherwise empty spaces between columns.

The early Koryŏ pagoda was executed in the Unified Silla style, although the roof stones were thinner and the number of eave corbels decreased to three or four. Then, after a short period, this style of pagoda changed drastically. The number of stories increased, the corbels on the roof stones became almost unrecognizable, and the height of each story was reduced. The Koryŏ pagoda became either an emasculated pagoda of the Unified Silla period or an unstable columnar silhouette. There are also towering octagonal pagodas as, for example, the one at Wŏlchŏng Temple. These were not revivals of the Koguryŏ type but a contemporary style imported from Sung China.

Toward the end of the Koryŏ the building of pagodas virtually came to a halt. One exception is the 10-story (12-metre) marble pagoda built in 1348 for the Wŏngak Temple in Kaesŏng (now in the Kyŏngbok Palace, Seoul). The pagoda stands on a cross-shaped, three-tiered platform. Every architectural detail from roof tiles to the bracket system is painstakingly reproduced, and numerous Buddhist figures in relief cover the entire surface of the pagoda.

Painting. Only about 10 examples of original Koryŏ painting are extant, and most of these are in Japan. They are mainly minor works on Buddhist themes except for several badly worn fragments of a hunting scene attributed to King Kongmin (1351–74) and two landscapes by other artists. There is little to be said about these isolated works except that they are in varying degrees in the style of Chinese painting of the Sung period (960–1279). Among the few examples of Koryŏ temple wall paintings are the Buddhistic images in the Chosa-dang (Founder's Hall) at Pusŏk Temple (1377) and the paintings of flowers in the Main Hall of the Sudŏk Temple (1308). Among the important examples of Koryŏ tomb painting is an image of a flying *deva* (from the 12th or 13th century) discovered in 1971 on the wall of a tomb at Kŏch'ang in southeastern Korea.

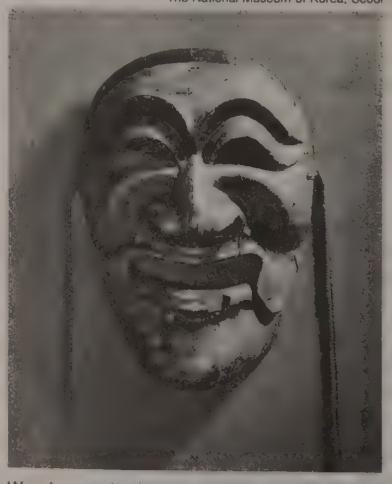
Sculpture. Compared with that of the Unified Silla period, Koryŏ sculpture shows a decline in both quantity and quality. However, before the decline a momentary surge of naturalism, a traditionally northern Korean quality, revitalized the period. Large images with imposing bodies and archaic smiles were successfully cast in iron, a medium not used since the late Unified Silla period. Direct copies from 8th-century Unified Silla models were often attempted. The colossal seated iron Buddha in the National Museum of Korea is the best example of this revival style. This image of the Buddha was clearly influenced by the large Śākyamuni of the Unified Silla cave temple of Sŏkkuram. Only the long narrow eyes, the sharpened nose, and a certain angularity in the treatment of the drapery give the Buddha a unique Koryŏ coldness that heralds the rather abstract quality found in later iron images.

In stone sculpture, also, the revival style is noticeable. The trend, however, was short-lived, and by the 12th century Koryŏ sculptors seem to have lost the art of working large, fully rounded figures in stone or metal. The decline in technique was manifested in the abstract tendency of certain figures of the middle of the Koryŏ period, such as the seated iron Buddha in Ch'ungju.

Although the sculpture produced by the major workshops suffered a decline, good sculptors could still be found in the countryside. One of the best known is the master who carved a set of wooden play masks for the village of Hahoe near Andong in southeastern Korea. The masks are marked by an exotic realism. The deep-set eyes are arranged asymmetrically so as to become mobile

Theatrical masks

The National Museum of Korea, Seoul



Wooden mask of a court servant, late Koryŏ period. In the National Museum of Korea, Seoul. Height 24.2 cm.

under the play of changing light and shade. The nose, very un-Korean, is extraordinarily long and aquiline. The separately made chin, like the nose, is massive. Models for these exotic masks must have come from China, as early as the T'ang dynasty, when elements of Persian and Central Asian art found their way into China. These Korean masks might well have served as the intermediary links through which the Japanese mask for the nō drama developed from original Chinese models.

Decorative arts. Traditional Koryŏ pottery was unglazed grayish stoneware in the Unified Silla tradition. By the end of the 10th century, however, the technique of high-fired, green-glazed porcelain of the Yüeh type was introduced from Chekiang province in southern China. After an initial period of imitation, Koryŏ potters, from about the mid-11th century or slightly earlier, started to produce their own distinctive kind of porcelain with a celadon glaze. Two main ceramic centres, at Kangjin and Puan, operated in southwestern Korea from the very beginning to the end of the Koryŏ period.

Celadon porcelain

The first period of Koryŏ celadon, from about 1050 to 1150, was the period of plain celadon ware. The "secret" colour of Koryŏ celadon, a greenish blue with a mysteriously deep tone, was regarded by the Sung Chinese as one of the "ten best things in the world." The potters of the first period appear to have been mainly concerned with the deep, lustrous colour and the formal beauty of the vessel, although they also used incised, engraved, or molded animal and floral patterns to decorate their vessels. Their specialties were animal- and fruit-shaped ewers and incense burners. White procelain of the Chinese *ying-ching* type also was produced during this period, though only in limited quantities.

The next 100 years, from 1150 to 1250, is the period of inlaid celadon ware. The technique of inlay on celadon is generally believed to have been invented about the mid-12th century. The idea of inlay may have come from a number of sources, but it is undoubtedly related to techniques of metal inlay that in turn were derived from inlaid lacquer. Whatever the origin, inlaid celadon was a Korean invention and unique to the Korean pottery of the 12th to the 15th century. In this technique, the freshly thrown vessel is left to dry to a leatherlike hardness. Designs are then incised or gouged out and filled with white or black clay. Sometimes, instead of the design, the background is scraped off and filled with black or white clay. During the initial stage, potters were still aware of the importance of glaze colour, despite the remarkable effect of inlaid designs. As time passed, however, they gradually inclined toward the decorative effect of designs, and the space occupied by the design came to dominate their work. The famous vase in the Kansong Art Museum, Seoul, is an outstanding example of this mature period of inlaid celadon.

From about 1250 to the end of the Koryŏ period in 1392 is the period of decline. The inlay technique continued, but the designs were loose and coarse and lacked the craftsmanship of the earlier pieces. The glaze colour is predominantly yellowish because an oxidizing fire was used. Crowded floral patterns painted in an iron type of underglaze became fashionable under the influence of Chinese pottery of the Yüan period (1206–1368).

The Koreans probably learned the technique of lacquer making from the Chinese at Nangnang during the early years of the Three Kingdoms period. It thenceforth became so popular that inlaid lacquer is almost completely a Korean specialty. The technique, although called "inlaid," is more accurately a polish-expose technique. Cut pieces of abalone or tortoiseshell, supplemented by silver or bronze wire, are pasted on the hemp or hemp-coated pinewood core with a thick coat of lacquer. Many layers of lacquer and special glue are then applied to the design until the shell layer is completely concealed. It is then polished with whetstone and charcoal until the surface of the design is revealed.

Inlaid lacquerware

Bronze temple bells continued to be cast, but they gradually were reduced in size, and the craftsmanship showed a remarkable decline from the Unified Silla period. A Koryŏ bell is distinguished by the outer edge of the crown, which characteristically is marked by a band of lotus petals that projects out obliquely. Images of outlined Buddhas and bodhisattvas around the trunk replaced the earlier flying *devas* (heavenly beings who are the guardians of Buddhism).

Important among the Koryŏ bronzes is the series of beautifully finished incense burners still treasured by many temples. These censers look like enlarged mounted cups with deep bowllike bodies, the mouth rims of which flare out horizontally to form a broad brim. The body is mounted on top of a conical stand with graceful concave side lines. The surface of the vessel is always covered with fluent, linear floral patterns or animated dragons inlaid with silver, which stand out strikingly against the shining black patinated background. The same techniques and decorative motifs also were used for making the artistically outstanding bronze mirrors typical of the Koryŏ period.

Chosŏn (Yi) period (1392–1910). In 1388 General Yi Sŏng-gye dethroned the pro-Mongol King Wu. Four years later, in 1392, General Yi proclaimed himself founder of the new Chosŏn dynasty (1392–1910) and moved the capital from Kaesŏng (Songdo) to Seoul. His policy was to maintain close political and cultural ties with Ming China (1368–1644). Buddhism, by then thoroughly corrupt, was displaced as the state religion by a puritanic Neo-Confucianism, then also on the ascendant in Ming China. Confucianism became the dominant influence on Korean thought, morals, and aesthetic standards. Chosŏn craftsmen and artisans, unable except occasionally to draw inspiration from imported Chinese art, were constrained to rely upon their own sense of beauty and perfection. Chosŏn artists, particularly in the decorative arts, showed a more spontaneous, indigenous aesthetic sense than the sophisticated aristocratic elegance of Koryŏ art.

In 1592 the Japanese general Toyotomi Hideyoshi invaded Korea. For many years the entire peninsula was a battlefield, and a tremendous amount of art was destroyed. The Japanese even carried off many Korean potters, who later managed to settle in the northern part of the island of Kyushu and become the founders of the Japanese porcelain industry. The Japanese invasion was soon followed by the Manchu, a Manchurian people, who later conquered China and established the Ch'ing dynasty (1644–1911/12). The two invasions left the Chosŏn government in a critically weakened condition, but they also inspired the rise of a strong nationalist sentiment among the Korean people. Concern focused on solving domestic social problems and on reviving and restoring confidence in Korean culture and identity. Scholars made efforts to develop practical knowledge and wisdom to improve life in Korea rather than studying "empty" Confucian theories. Painters for the first time showed profound interest in the landscape and daily life of Korea, and Chosŏn art of the 17th to 18th century demonstrated a marked Korean character and flavour. This florescence of Chosŏn art ended after only two centuries, however, because of the lack of public and private patronage, the lack of inspiration, and the apathy and poverty that occurred as the dynasty itself entered the last phase of its history.

Nevertheless, this period left abundant artistic remains. There are many palace and temple buildings, although few date to before the Japanese invasion. Buddhist images were usually made of wood instead of bronze and iron, and granite was rarely used for sculpture. Among the secular arts, painting and ceramics were the most important. The Chosŏn government maintained an Office of Painting, or Imperial academy of painting (Tohua-sŏ), and the government also operated an official kiln that alone was authorized to produce blue-and-white porcelain. Local private kilns also mass-produced large amounts of ceramics. The Chosŏn dynasty was finally terminated when Japan annexed Korea in 1910.

Architecture. Many large palace and temple buildings are preserved from the Chosŏn period, particularly those built from the 17th century on. The *chusimp'o*, the columnhead bracket style of the Koryŏ period, continued during the early part of this period. But the dominant architectural style of the Chosŏn period was the *tap'o*, or the intercolumnar bracket style. At least five large palaces in Seoul alone date from the beginning of the period. The

Kyŏngbok Palace

largest and most important is the Kyŏngbok Palace, originally a complex of more than 100 buildings. The entire palace was burned down during the Japanese invasion in the late 1500s but it was reconstructed between 1865 and 1867. Kŭnjŏng-jŏn, the palace's throne hall, built in the decorative *tap'o* style, is the largest wooden building in Korea. Among temples, the main halls of Muwi Temple, Kaisim Temple, and Pongjong Temple belong to the early Chosŏn period, while the grand main hall of the Hua'ŏm Temple represents the later Chosŏn *tap'o* architecture. The only important Chosŏn pagoda is the marble pagoda (1467) in Seoul's Pagoda Park.

Painting. Chosŏn painting up to the end of the 16th century was dominated by court painters attached to the Office of Painting. Their style followed that of Chinese professional court painters, the so-called Northern school of Chinese painting, and was thus variably influenced by the Kuo Hsi school of the Northern Sung, the Ma-Hsia school of the Southern Sung, and the Che school of Ming China. Famous painters of the period are An Kyŏn, Ch'oe Kyŏng, and Yi Sang-cha. An Kyŏn's best work, "Dream Journey to the Peach Blossom Land" (1447; Tenri University Collection, Japan), executed in the heroic style of the Northern Sung, is a horizontal scroll depicting fantastic mountains and streams dotted with peach blossoms.

Yi Am, Shin Sa-im-dang, and Yi Chŏng are the better scholar-painters of the first period. Unlike the professional court painters, who made Chinese landscapes their specialty, these amateur scholar-painters devoted themselves to painting the so-called Four Gentlemen—the pine tree, bamboo, plum tree, and orchid—as well as such traditionally popular subjects as birds, insects, flowers, and animals.

In the early 17th century the Southern school of China, exemplified by Mi Fu, Shen Chou, Wen Cheng-ming, and others, strongly influenced Korean painters, particularly the nonprofessional scholar-painter. Professional academic painters followed the academic court style of Ch'ing China, which was itself a sort of formalized Southern style. The "expressionistic" and individualistic Ch'ing style of the Eight Eccentrics of Yang-chou, however, did not find followers in Chosŏn Korea. Concurrent with the imitation of Chinese painting styles was a movement to achieve in approach and effect a truly Korean expression. The works of Cho Sok, noted for their thin wash of ink, displayed the melancholy of Chosŏn society. Chŏng Sŏn, a great Chosŏn master, disliked the imaginary Chinese-style landscapes and devoted himself instead to the real Korean landscape. His favourite theme was the rugged peaks of Mount Kumgang (Diamond Mountain) in central eastern Korea. To depict rocky cliffs and soaring forests, he devised his characteristic "wrinkles" of forceful vertical lines. The trend toward a national style, established by Chŏng Sŏn and others, was followed by Kim Hong-do, Shin Yun-bok, and Kim Tŭk-shin, who all painted national scenes of daily life in Korea with a realism that often bordered on caricature. Among these the greatest master was Kim Hong-do, better known under the name of Tanwŏn. He also painted many Korean landscapes and was the first Korean painter to draw his genre themes from the life of the lower classes. He seems also to have been the first Korean painter to try to depict human muscles.

Development of a Korean style

In the 19th century, Cho Chŏng-kyu, Hŏ Yu, Chang Sŭng-ŏp, and Cho Sŏk-chin were among the more active professional painters. Their paintings were mannered and exhibited an academic style lacking individuality. They painted many excellent portraits of Korean dignitaries in an indigenous style, but otherwise they returned to the old clichés of pseudo-Chinese painting. During this century the first influence of European art on the court painters may be seen in their use of shading techniques in painting portraits.

The activities of a short-lived group of painters who followed the *wen-jen hua,* or Chinese literati style of painting, should be seen against the general decline of the academic style of the 19th century. All of them were men of learning and genuine taste who grasped the spirit of such great Chinese masters of the Yüan period as Ni Tsan and Huang Kung-wang. The most distinguished members of this group were Kim Chŏng-hŭi, the great calligrapher, who painted little, and Chŏn Ki, who died young.

Sculpture. By the beginning of the Chosŏn period, the production of traditional religious sculpture had virtually died out because of the importance of Confucianism, the new state religion. The Buddhist images that were produced are mostly made of wood and are artistically undistinguished. At first Chosŏn sculpture followed the late Koryŏ style and early Ming sculpture of the late 14th and 15th centuries. A Chosŏn Buddha is characterized by a rounded late Unified-Silla-type head with a flat, emotionless face. The body is a simple, stolid mass covered with a loose, yet leatherlike, thick robe. Drapery folds are depicted in a formalized, schematic series of plaits.

Decline of Buddhist sculpture

Secular sculpture included the series of stone statues of civil and military officers that were erected in front of the tombs of members of the royal family and other dignitaries.

Decorative arts. Although a wide variety of decorative arts flourished in the Chosŏn period, the making of pottery and porcelain was especially important. One of the most popular types of ceramic ware produced was called *punch'ŏng,* the Korean term for a type of pottery known in Japan as *mishima.* This is a simplified form of *punjang ch'ŏngja,* or slip-decorated celadon. The slip-decoration includes inlaid, incised, and stamped patterns filled with white clay, and also the overall application of a white coating under the celadon glaze. Incision and painting in underglaze iron also are applied at times over the white coating. The technique evolved (or degenerated) from Koryŏ inlaid celadon, which had become coarse and rough in its final stages. The early Chosŏn potters invented a new device to produce the inlay effect more quickly and easily. A wooden or clay stamp with tiny embossed dots was used to produce designs of closely spaced depressed dots over the entire surface of a vessel in a matter of minutes. White clay was then rubbed into the dots and the excess clay wiped off. There are, however, Chosŏn pieces done in the traditional inlay technique, and they can be instantly distinguished from late Koryŏ wares by their crude and unsophisticated designs (floral as well as animal) and the stained grayish green colour of their glaze.

Punch'ŏng ware

The predominant *punch'ŏng* shapes are small or medium-size wine bottles and tea and rice bowls. Many were produced under orders from government offices, but their mass production suggests that there may have been increasing demand from the general public. *Punch'ŏng* pottery was loved by Japanese masters of the tea ceremony. The Hideyoshi invasion put an end to the lingering Koryŏ inlaid celadon once and for all. The *punch'ŏng* stamping technique, however, is still used on the island of Okinawa, south of Japan.

White porcelain, which may have been inspired by the Yüan and Ming blue-and-white porcelain ware of China, has remained as the most practical ware for ordinary Koreans. White porcelain wares of the pre-16th-century Chosŏn dynasty are covered with a milky-white devitrified glaze. They were produced at hundreds of central and local kilns, but the best pieces came from the Kwangju kilns south of Seoul during the 15th century. Besides being the

most commonly used, white porcelain alone was permitted as ritual ware for Confucian rites and ancestor worship.

Blue-and-white porcelain, inspired by early Ming models, appeared in Chosŏn Korea by the mid-15th century, and Chosŏn potters soon developed a distinct Korean or Chosŏn style of blue-and-white wares. Vessel forms are sturdy and simple; and the decoration, which is naive and refreshing, is kept to a minimum to emphasize the white background—a design tendency also observed on Chosŏn white porcelain with underglaze iron decoration. Chosŏn blue-and-white wares were produced by government-operated kilns in the Kwangju area near Seoul, mainly for palace and high government officials. In later years, vessels of low quality became accessible to commoners.

Modern period. The impact of modern Western art began to be felt during the last decades of the 19th century, when Korea was forced to enter into treaties with foreign governments. In 1900 a British architect, at the request of the Chosŏn government, designed the renaissance revival Tŏksu Palace in Seoul. The stone building, which later became the National Museum, was completed in 1909. With the construction of Western-style buildings in Seoul came the need for European furnishings. Glass was used in some doors in the palace and certain public buildings, and from 1900 electric lamps were installed. Just as the Koreans were beginning to familiarize themselves with such Western architectural concepts as spaciousness and convenience, the Japanese took over the government, bringing a new set of influences. During the 35-year period of the Japanese occupation (1910–45), some Koreans lived in strange, hybrid houses of Euro-Japanese style, but most clung to traditional Korean-style houses. Architects and carpenters capable of working in the traditional bracket system became so scarce that, after the liberation in 1945, the Korean government had to search out the few surviving older architects and set them to training younger ones, not so much to design new buildings in the traditional manner as to ensure that existing national cultural properties would be properly preserved.

European and Japanese influence

At the beginning of the Japanese occupation, traditional Korean painting was led by Cho Sŏk-chin and An Chung-shik. Cho was the last court painter of the Chosŏn dynasty, and An the last gentleman painter. But their styles were similar in their pursuit of the enervated southern Chinese style of the Ch'ing period, with its emphasis on fingertip technique. In 1911 the former Korean Imperial family set up an academy of painting to foster the traditional style, and, though it dissolved in 1919, a number of important painters were trained. By the 1930s the pattern of Korean painting began to change under the impact of both Japanese and European influences. In 1922 the Japanese had inaugurated an annual exhibition for Korean artists, designed to promote a new academic style. The only modern facilities for studying painting, whether Asian or Western, were Japanese. Despite the resistance of traditionalists, the Japanese impact was irresistible. Prominent painters during this period were Kim Ŭn-ho, Yi Sang-bŏm, Ko Hŭi-dong, Pyŏn Kwan-shik, and No Su-hyŏn. After World War II traditional painting began to assume a modern mode of expression, as may be seen in the works of a group of radical painters such as Kim Ki-ch'ang, Pak Nae-hyŏn, and Pak No-su. All of these artists were highly trained in the traditional mediums of ink and watercolour painting. Their paintings reflect a bold sense of composition and colour and also have the quality of genuine abstract art.

Introduction of oil painting

The introduction of the Western style via China in the 18th century had gone almost unnoticed. In 1899 the commissioning of a Dutch artist to paint the portraits of the king and the crown prince affronted the traditional court painters. When Ko Hŭi-dong returned from a period of study of oil painting in Japan, he was so ridiculed in public whenever he went out to sketch in oil that he finally gave up and returned to traditional painting. Nevertheless, several students followed his lead by going to Tokyo to study oil painting, and soon the new art became the dominant field of activity. Throughout the Japanese occupation, the main trend of Korean oil painting was the modest, representational school that had its roots in Impressionism. Among the outstanding painters in this style were Yi Chong-u, To Sang-bong, Kim Insŭng, and Pak Tŭk-sun. This academic-style painting filled the government-sponsored annual art exhibitions in Seoul into the early 1960s. But then the efforts of a group of nonrepresentational painters including Kim Hwan-ki, Yu Yŏng-guk, and Kwon Ok-yŏn reversed the trend and persuaded the government to establish an independent section in the exhibition for abstract art. The number of students studying abroad increased, and the influence of international-style painting progressed rapidly. In the last decades of the 20th century all kinds of European and American styles were introduced to artists in South Korea and experimented with. By contrast, in North Korea, artists have been restricted to traditional, conservative styles with which to represent an extremely limited range of subjects for the express purpose of promoting political propaganda. (W.-Y.K.)

Japanese visual arts

GENERAL CHARACTERISTICS

Most Japanese art bears the mark of extensive interaction with or reaction to outside forces. Buddhism, which originated in India and developed throughout Asia, was the most persistent vehicle of influence. It provided Japan with an already well-established iconography and also offered perspectives on the relationship between the visual arts and spiritual development. Notable influxes of Buddhism from Korea occurred in the 6th and 7th centuries. The Chinese T'ang international style was the focal point of

Japanese artistic development in the 8th century, while the iconographies of Chinese Esoteric Buddhism were highly influential from the 9th century. Major immigrations of Chinese Ch'an (Japanese: Zen) Buddhist monks in the 13th and 14th centuries and, to a lesser degree, in the 17th century placed indelible marks on Japanese visual culture. These periods of impact and assimilation brought not only religious iconography but also vast and largely undigested features of Chinese culture. Whole structures of cultural expression, ranging from a writing system to political structures, were presented to the Japanese.

Various theories have thus been posited which describe the development of Japanese culture and, in particular, visual culture as a cyclical pattern of assimilation, adaptation, and reaction. The reactive feature is sometimes used to describe periods in which Japanese art's most obviously unique and indigenous characteristics flourish. The notion of cyclical assimilation and then assertion of independence requires extensive nuancing, however. It should be recognized that, while there were periods in which either continental or indigenous art forms were dominant, usually the two forms coexisted.

Importance of nature

Another pervasive characteristic of Japanese art is an understanding of the natural world as a source of spiritual insight and an instructive mirror of human emotion. An indigenous religious sensibility that long preceded Buddhism perceived that a spiritual realm was manifest in nature. Rock outcroppings, waterfalls, and gnarled old trees were viewed as the abodes of spirits and were understood as their personification. This belief system endowed much of nature with numinous qualities. It nurtured, in turn, a sense of proximity to and intimacy with the world of spirit as well as a trust in nature's general benevolence. The cycle of the seasons was deeply instructive and revealed, for example, that immutability and transcendent perfection were not natural norms. Everything was understood as subject to a cycle of birth, fruition, death, and decay. (Imported Buddhist notions of transience were thus merged with the indigenous tendency to seek instruction from nature.)

Attentive proximity to nature developed and reinforced an aesthetic that generally avoided artifice. In the production of works of art, the natural qualities of constitutive materials were given special prominence and understood as integral to whatever total meaning a work professed. When, for example, Japanese Buddhist sculpture of the 9th century moved from the stucco or bronze T'ang models and turned for a time to natural, unpolychromed woods, already ancient iconographic forms were melded with a preexisting and multileveled respect for wood.

Union with the natural was also an element of Japanese architecture. Architecture seemed to conform to nature. The symmetry of Chinese-style temple plans gave way to asymmetrical layouts that followed the specific contours of hilly and mountainous topography. The borders existing between structures and the natural world were deliberately obscure. Elements such as long verandas and multiple sliding panels offered constant vistas on nature—although the nature was often carefully arranged and fabricated rather than wild and real.

Preference for imperfections

The perfectly formed work of art or architecture, unweathered and pristine, was ultimately considered distant, cold, and even grotesque. This sensibility was also apparent in tendencies of Japanese religious iconography. The ordered hierarchical sacred cosmology of the Buddhist world generally inherited from China bore the features of China's earthly imperial court system. While some of those features were retained in Japanese adaptation, there was also a concurrent and irrepressible trend toward creating easily approachable deities. This usually meant the elevation of ancillary deities such as Jizō Bosatsu or Kannon Bosatsu to levels of increased cult devotion. The inherent compassion of supreme deities was expressed through these figures and their iconography.

The interaction of the spiritual and natural world was also delightfully expressed in the many narrative scroll paintings produced in the medieval period. Stories of temple foundings and biographies of sainted founders were replete with episodes describing both heavenly and demonic forces roaming the earth and interacting with the populace on a human scale. There was a marked tendency toward the comfortable domestication of the supernatural. The sharp distinction between good and evil was gently reduced, and otherworldly beings took on characteristics of human ambiguity that granted them a level of approachability, prosaically flawing the perfect of either extreme.

Even more obviously decorative works such as the brightly polychromed overglaze enamels popular from the 17th century selected the preponderance of their surface imagery from the natural world. The repeated patterns found on surfaces of textiles, ceramics, and lacquerware are usually carefully worked abstractions of natural forms such as waves or pine needles. In many cases pattern, as a kind of hint or suggestion of molecular substructure, is preferred to carefully rendered realism.

The everyday world of human endeavour has been carefully observed by Japanese artists. For example, the human figure in a multiplicity of mundane poses was memorably recorded by the print artist Hokusai (1760–1849). The quirky and humorous seldom eluded the view of the many anonymous creators of medieval hand scrolls or 17th-century genre screen paintings. Blood and gore, whether in battle or criminal mayhem, were vigorously recorded as undeniable aspects of the human. Similarly, the sensual and erotic were rendered in delightful and uncensorious ways. The reverence and curiosity about the natural extended from botany to every dimension of human activity.

In summary, the range of Japanese visual art is extensive, and some elements seem truly antithetical. An illuminated sutra manuscript of the 12th century and a macabre scene of ritual disembowelment rendered by the 19th-century print artist Tsukioka Yoshitoshi can be forced into a common aesthetic only in the most artificial way. The viewer is thus advised to expect a startling range of diversity. Yet within that diverse body of expression certain characteristic elements seem to be recurrent: art that is aggressively assimilative; a profound respect for nature as a model; a decided preference for delight over dogmatic assertion in the description of phenomena; a tendency to give compassion and human scale to religious iconography; and an affection for materials as important vehicles of meaning.

STYLISTIC AND HISTORICAL DEVELOPMENT

Formative period. The terminology and chronology used in describing pre- and protohistoric Japan is generally agreed to be that of a Paleolithic, or Pre-Ceramic, stage dating from approximately 30,000 BC (although some posit an initial date as early as 200,000 BC); the Jōmon period (*c.* 10,500 BC–3rd century BC), variously subdivided; the Yayoi period (3rd century BC–3rd century AD); and the Tumulus, or Kofun, period (3rd century AD–AD 710).

Paleolithic stage. Until about 18,000 years ago, what is now known as the Japanese archipelago was connected to the East Asian landmass at several points. Similarly, the now divided islands were also joined at some points. These land passages account for the discovery of the remains of both prehistoric animals and microlithic cultures (but no pottery) of types usually associated with the continent. Continued warming trends, beginning about 20,000 years ago, eventually raised sea levels, thus cutting off all but the northern passage from Siberia.

The earliest human populations on the archipelago had subsisted on hunting and foraging, but with the warming trends the bounty of large, easy-to-fell animals began to die out while the variety and density of plant life rose dramatically. The increase in the number of sites discovered dating from 15,000 to 18,000 years ago suggests that once-roaming bands of hunter-gatherers were becoming gradually more sedentary and less dependent on foraging. As further evidence, the remains of charred cooking stones, indicating prolonged periods of use, have been discovered, and manufactured projectile points, including worked obsidian, dating from this period provide evidence of the people's adaptive skill in bringing down smaller, swifter game.

Mesolithic stage

Approximately 12,000 to 10,000 years ago, the definitive conditions for what is termed a Mesolithic stage became

apparent: a hunting culture employed microliths and, in addition, manufactured pottery. Just as the use of microlith weapons increased as a result of a decline in the numbers of big game, the manufacture of pottery was probably necessitated by a food supply crisis that required a means of storage and, perhaps, a method for boiling or otherwise cooking plants.

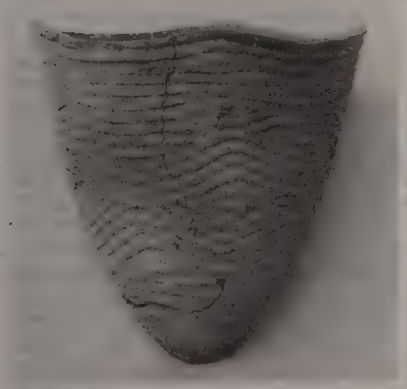
Jōmon period. Beginning in 1960, excavations of stratified layers in the Fukui Cave, Nagasaki prefecture in northwestern Kyushu, yielded shards of dirt-brown pottery with applied and incised or impressed decorative elements in linear relief and parallel ridges. The pottery was low-fired, and reassembled pieces are generally minimally decorated and have a small round-bottomed shape. Radiocarbon dating places the Fukui find to approximately 10,500 BC, and the Fukui shards are generally thought to mark the beginning of the Jōmon period. This early transitional period seems to lack convincing evidence of plant cultivation which would, along with microlith and pottery production, allow it to meet the criteria for a Neolithic culture.

The name Jōmon is a translation for "cord marks," the term the American zoologist Edward Sylvester Morse used in his book *Shell Mounds of Omori* (1879) to describe the distinctive decoration on the prehistoric pottery shards he found at Ōmori in southwestern Tokyo. Other names, such as "Ainu school pottery" and "shell mound pottery," were also applied to pottery from this period, but, after some decades, although cord marks are not the defining decorative scheme of the type, the term *jōmon* was generally accepted. The earliest stage of the period, to which the Fukui shards belong, has been given various names, including Incipient Jōmon and Subearliest Jōmon. Some scholars even call it Pre-Jōmon and argue that life during this stage showed only a slight advance from that of the Paleolithic. In 1937 Yamanouchi Sugao suggested the subdivisions Earliest, Early, Middle, Late, and Latest Jōmon for the remainder of the period. With refinements in chronology and the addition of some subsets, this terminology remains in use.

Earliest Jōmon

The period called Earliest, or Initial, Jōmon (*c.* 7500–5000 BC) produced bullet-shaped pots used for cooking or boiling food. The tapered bases of the pots were designed to stabilize the vessels in soft soil and ash at the centre of a fire pit. Decorative schemes included markings made by pressing shells and cords or by rolling a carved stick into the clay before it hardened. The shapes and worked surface textures of these early vessels suggest their probable precursors—leather, bark, or woven reed containers reinforced with clay. The Hanawadai site in Ibaraki prefecture constitutes the first recognized Earliest Jōmon community.

Early Jōmon (5000–3500 BC) sites suggest a pattern of increased stabilization of communities, the formation of small settlements, and the astute use of abundant natural resources. A general climatic warming trend encouraged habitation in the mountain areas of central Honshu as well as coastal areas. Remains of pit houses have been found arranged in horseshoe formations at various Early Jōmon sites. Each house consisted of a shallow pit with a tamped earthen floor and a grass roof designed so that rainwater runoff could be collected in storage jars.



Earliest Jōmon vessel, clay, *c.* 5000 BC. In the Hakodate Municipal Museum, Japan. Height 16.6 cm.

Hakodate Municipal Museum, Japan

Early Jōmon vessels generally continued the fundamental profile of a cone shape, narrow at the foot and gradually widening to the rim or mouth, but most had flat bottoms, a feature found only occasionally in the Earliest Jōmon period. The characteristic markings were impressed on damp clay with a twisted cord or cord-wrapped stick to produce a multiplicity of patterns. Other techniques, including shell impressions, were also used. In addition to the flared-mouth jars, shallow bowls and narrow-necked bottles were also introduced. The discovery of increasing varieties of flat-bottomed vessels appropriate for cooking, serving, and providing storage on flat earthen floors correlates with the evidence of the gradual formation of pit-house villages.

While pottery was the main form of visual expression in the Early Jōmon period, wood carving and lacquering are among the other significant forms of expression, suggesting the development of a more complex culture. Ropes, reed baskets, and wooden objects have been found at the Torihama mound site in Fukui prefecture. The oldest known examples of Japanese lacquerware—bowls and a comb—are also from this site.

Middle Jōmon

The Middle Jōmon period (3500–2500 BC) witnessed a dramatic increase both in population and in the number of settlements. Signs of incipient agriculture can be detected in this period, but this may have involved settling near wild plants and storing them effectively. Vessels began to take on heavy decorative schemes employing applied clay. The use of vessels for purposes beyond cooking and storage is also noted. Clay lamps, drum shells, and figurines strongly suggest an expanding use of the medium for religious symbolic expression. Fertility images of clay female figurines with exaggerated breasts and hips and of stone phalli have been located on stone platforms placed on the northwest side of dwellings. These platforms may represent early household altars. During this period jars were used for burial and were characteristically damaged so as to prohibit any other type of use.

Three distinct vessel styles were produced during the Middle Jōmon. The Katsusaka type, produced by mountain dwellers, has a burnt-reddish surface and is noted especially for extensive and flamboyant applied decorative schemes, some of which may have been related to a snake cult. The Otamadai type, produced by lowland peoples, was coloured dirt-brown with a mica additive and is somewhat more restrained in design. The Kasori E type has a salmon-orange surface. During this period a red ocher paint was introduced on some vessel surfaces, as was burnishing, perhaps in an attempt to reduce the porosity of the vessels.

In the Late Jōmon (2500–1000 BC) colder temperatures and increased rainfall forced migration from the central mountains to the eastern coastal areas of Honshu. There is evidence of even greater interest in ritual, probably because of the extensive decrease in population. From this time are found numerous ritual sites consisting of long stones laid out radially to form concentric circles. These stone circles, located at a distance from habitations, may have been related to burial or other ceremonies. Previously disparate tribes began to exhibit a greater cultural uniformity. Artifacts discovered in diverse coastal areas show a uniform vocabulary of expression and a consistent decorative system, suggesting more sophisticated methods of manufacturing, such as controlled firing of pottery, and increased specialization. The technique of erased cord marking, in which areas around applied cord marks were smoothed out, was increasingly used. This relates to a more general practice or interest in polished pottery surfaces. A unique black polished pottery type called Goryo has been found in central Kyushu. Some scholars suggest that this may in some way be imitative of Chinese black Lung-shan pottery (*c.* 2200–1700 BC).

Latest Jōmon

Evidence from the Latest, or Final, Jōmon (*c.* 1000–3rd century BC) suggests that inhospitable forces, whether contagious disease or climate, were at work. There was a

Clay figurine dating from Latest Jōmon period, excavated at Ebisuda, Miyagi prefecture. In the collection of Tōhoku University, Sendai, Japan. Height 35.6 cm.

By courtesy of the Archaeological Seminar, Tohoku University, Sendai, Japan

considerable decrease in population and a regional fragmentation of cultural expression. Particularly noteworthy was the formation of quite distinct cultures in the north and south. The discovery of numerous small ritual implements, including pottery, suggests that the cultures developing in the north were rigidly structured and evinced considerable interest in ritual.

More than 50 percent of the Latest Jōmon sites are in northern Honshu, where significant quantities of polished or burnished pottery and lacquerware have been found. In fact, it is from this time that lacquer working—used for both decorative and waterproofing purposes—begins to emerge as a distinct craft. In general, the northern distinction between utilitarian and ritual ware became more pronounced, and the ritual ware became more elaborately conceived. The latter phenomenon is clearly illustrated by the unusual clay figurines with enormous goggle eyes that are characteristic of the Latest Jōmon.

In the south mobility and informality were the emerging characteristics of social organization and artistic expression. In distinction to the northern culture, the south seemed more affected by outside influences. Indeed, the incursions of continental culture would, in a few centuries, be based in the Kyushu area.

Yayoi period. In 1884 a shell mound site in the Yayoi district of Tokyo yielded pottery finds that were initially thought to be variants of Jōmon types but were later linked to similar discoveries in Kyushu and Honshu. Scholars gradually concluded that the pottery exhibited some continental influences but was the product of a distinct culture, which has been given the name Yayoi.

Both archaeological and written evidence point to increasing interaction between the mainland and the various polities on the Japanese archipelago at this time. Indeed, the chronology of the Yayoi period (3rd century BC–3rd century AD) roughly corresponds with the florescence of the aggressively internationalized Chinese Han dynasty (206 BC–AD 220).

The Yayoi culture thus marked a period of rapid differentiation from the preceding Jōmon culture. Jōmon, a hunting-and-gathering culture with possibly nascent forms of agriculture, experienced changes and transitions primarily in reaction to climatic and other natural stimulants. Yayoi, however, was greatly influenced by knowledge and techniques imported from China and Korea. The impact of continental cultures is decidedly clear in western Japan from about 400 BC, when primitive wet-rice cultivation techniques were introduced. Attendant to the emerging culture based on sedentary agriculture was the introduction of a significant architectural form, the raised thatched-roof granary. Bronze and iron implements and processes of metallurgy were also introduced and quickly assimilated, as the Yayoi people both copied and adapted types and styles already produced in China and Korea. Thus, while the decorative instincts of the Jōmon culture were limited primarily to the manipulation of clay, a variety of malleable materials, including bronze, iron, and glass, were increasingly available to artisans of the Yayoi period. The introduction of these various technologies, the development of a stable agricultural society, and the growth of a complex social hierarchy that characterized the period became the springboards for various forms of creative expression and provided increasing opportunities for the development of artistic forms.

Chinese and Korean influence

The Yayoi period is most often defined artistically by its dramatic shift in pottery style. The new type of pottery, reflecting continental styles, was made first in western Japan. It then moved eastward and became assimilated with existing Jōmon styles. Jōmon pottery was earthenware formed from readily available sedimentary clay and was generally stiff. Yayoi pottery was formed from a fine-grained clay of considerable plasticity found in the delta areas associated with rice cultivation. It was smooth, reddish orange in colour, thinly potted, symmetrical, and minimally decorated. The simpler, more reserved styles and forms emulated Chinese earthenware. It was also at this time that pottery began to be produced in sets, including pieces made for the storing, cooking, and serving of food.

In addition to the characteristic pottery that gave its site name to the period, the production of metal objects, particularly the *dōtaku* bells, represents a significant artistic manifestation of the Yayoi period. The *dōtaku* were cast in bronze and imitative of a Chinese musical instrument. More than 400 indigenously produced *dōtaku* have been discovered in Japan. These bells range from 4 to 50 inches in height. Their quality suggests a rather advanced state of technical acumen. Figural and decorative relief bands on these bells offer some, albeit highly interpretive, insights into Yayoi culture and suggest that shamanism was the dominant religious modality. The *dōtaku* appear not to have been used as musical instruments in Japan. Instead, like the bronze mirrors and other distinguished

Dōtaku bells

Dōtaku (bell-shaped bronze) with design of whirlpools, excavated from Uzumora, Hyōgo prefecture, Yayoi period. In the Tokyo National Museum.

and precious implements transferred and adapted from Chinese and Korean forms, the *dōtaku* took on talismanic significance, and their possession implied social and religious power.

Tumulus, or Kofun, period. About AD 300 there appeared new and distinctive funerary customs whose most characteristic feature was chambered mound tombs. These tumuli, or *kofun* ("old mounds"), witnessed significant variations over the following 400 years but consistently dominated the period to which they gave their name. Some authorities have suggested that the development of these tombs was a natural evolution from a Yayoi-period custom of burial on high ground overlooking crop-producing fields. While partially convincing, this theory alone does not account for the sudden florescence of mound tombs, nor does it address the fact that some aspects of the tombs are clearly adaptations of a form preexisting on the Korean peninsula. Indeed, implements and artifacts discovered within these tombs suggest a strong link to peninsular culture.

Changes in tomb structure, as well as the quantity, quality, and type of grave goods discovered, offer considerable insight into the evolution of Japan's sociopolitical development from a group of interdependent agricultural communities to the unified state of the early 8th century. Of course, the material culture of the Kofun period extended far beyond the production of funerary art. For example, it is in this time that an essential form of Japanese expression, the Chinese writing system, made its appearance on the archipelago—a fact known from such evidence as inscribed metal implements. This system had a profound and comparatively quick influence not only on written language but also on the development of painting in Japan. Nevertheless, tombs are the repositories of the period's greatest visual achievements and are excellent indicators of more general cultural patterns at work. And, in that wider context, three distinct shifts in tomb style can be discerned that define the chronology of the period: Early Kofun of the 4th century, Middle Kofun covering the 5th and early 6th centuries, and Late Kofun, which lasted until the beginning of the 8th century and during which tomb burials were gradually replaced by Buddhist cremation ceremonies. The Late Kofun roughly coincides with the periods known to art historians as the Asuka (mid-6th century–645) and the Hakuhō (645–710).

Tombs of the Early Kofun period made use of and customized existing and compatible topography. When viewed from above, the tomb silhouette was either a rough circle or, more characteristically, an upper circle combined with a lower triangular form, suggesting the shape of an old-fashioned keyhole. The tombs contained a space for a wooden coffin and grave goods. This area was accessed through a vertical shaft near the top of the mound and was sealed off after burial was completed. The deceased were buried with materials that were either actual or symbolic indicators of social status. The grave goods were intended, as well, to sustain the spirit in its journey in the afterlife. They included bronze mirrors, items of jewelry made from jade and jasper, ceramic vessels, and iron weapons. Adorning the summit of the mound and at points on the circumference midway, at the base, and at the entrance to the tomb were variously articulated clay cylinder forms known as *haniwa* ("clay circle").

Haniwa sculpture

Haniwa were an unglazed, low-fired, reddish, porous earthenware made of the same material as a type of daily-use pottery called *haji* ware. These clay creations were shaped from coils or slabs and took the form of human figures, animals, and houses. The latter shape was usually set at the peak of the burial hillock. Many attempts have been made to interpret the function of *haniwa.* They seem to have served both as protective figures and as some type of support for the deceased in the afterlife. There is some suggestion that, similar to tomb figurines found in other cultures, they symbolized a retinue of living servants who might otherwise have been sacrificed upon the demise of their master. They are regionally distinctive and show a stylistic development from the decidedly schematic to realistic.

Haniwa horse, clay, 5th–6th century. In the Tokyo National Museum. Height 83.8 cm.

Another type of ceramic prominent in the Kofun period was *sue* ware. Distinct from *haji* ware, it was high-fired and in its finished form had a gray cast. Occasionally, accidental ash glazing is found on the surface. Until the 7th century, *sue* ware was a product reserved for the elite, who used it both for daily ware and on ceremonial occasions. *Sue* ware was more closely identified with Korean ceramic technology and was the precursor for a variety of medieval Japanese ceramic types. Interestingly, both *haji* and *sue* ware found roles in funerary art.

After the 4th century, tomb builders abandoned naturally sympathetic topography and located mounds in clusters on flat land. There are differences in mound size, even within the clusters, suggesting levels of social status. The scale of these tombs, together with construction techniques, changed considerably. The tomb generally assumed to be that of the late 4th-century emperor Nintoku, located near the present-day city of Ōsaka, measures nearly 1,600 feet

Mausoleum of Nintoku, at Sakai, largest of the "keyhole" type tombs of the Tumulus, or Kofun, period. Circumference 2,718 m, height 21 m.

By courtesy of the International Society for Educational Information,Tokyo

in length and covers 80 acres (32 hectares). It is alternately surrounded by three moats and two greenbelts. Approximately 20,000 *haniwa* were thought to have been placed on the surface of this huge burial mound.

In the later part of the 5th century, the vertical shaft used to access the early pit tomb was replaced by the Korean-style horizontal corridor leading to a tomb chamber. This made multiple use of the tomb easier, and the notion of a family tomb came into existence. Also notable from the 5th century is the archaeological evidence of horse trappings and military hardware in tombs. *Haniwa* representing warriors and stylized military shields are also prominent. Records of diplomatic and military forays combine with the grave goods of the period to suggest a strong military cast to 5th- and 6th-century culture. However, in time these accoutrements of war and symbols of physical power are found in ancillary tombs rather than in the grave sites of known leaders. This suggests a gradual consolidation of power and the formation of a specialized military service within the kingdoms.

Japan's close relationship with Korean and Chinese cultures during the Kofun period effected an influx of peninsular craftsmen. This is reflected in the production of *sue* ware mentioned above and in the high quality of metalwork achieved. Mirrors are a particularly fine example of the development of metal craft. The typical East Asian mirror of the time is a metal disk brought to a high reflective finish on one side and elaborately decorated on the reverse. Such mirrors did not originate in Japan but seem to have been made and used there for religious and political purposes. The dominant Japanese creation myth describes the Sun Goddess, Amaterasu Omikami, being coaxed from hiding by seeing her reflection in a mirror. This may well have imparted a magico-religious quality to mirrors and caused them to be understood as authority symbols. Of particular note is the so-called *chokkomon* decorative scheme found on some of these mirrors and on other Early Kofun metalwork. *Chokkomon* means "patterns of straight line and arcs," and the motif has also been found chiseled on a wall in a Late Kofun tomb at the Idera tomb in Kyushu. It has been suggested that the abstract interweaving pattern may symbolize rope binding the dead to the tomb, an aspect of Chinese cosmology of the Han dynasty.

Metalwork

Late Kofun tombs are characterized by schemes of wall decoration within the burial chambers. Two especially important tombs have been excavated in the area just to the south of present-day Nara. The Takamatsu tomb (1972) and the Fujinoki tomb (1985) suggest high levels of artistic achievement and a sophisticated assimilation of continental culture. The Takamatsu tomb is noted for its wall paintings containing a design scheme representing a total Chinese cosmology. Included are especially fine female figure paintings. At Fujinoki exquisite and elaborate metalwork, including openwork gold crowns, a gilt bronze saddle bow, and gilt bronze shoes, was discovered. Design motifs show evidence of Chinese, Central Asian, and Indian sources.

Asuka period. The Asuka period was a time of transformation for Japanese society. It is named for the Asuka area at the southern end of the Nara (Yamato) Basin (a few miles to the south of the present-day city of Nara), which was the political and cultural centre of the country at the time. From there, the imperial court ruled over a loose confederation of rival clans, the most powerful of which were the Soga, Mononobe, and Nakatomi.

Japan's interest in and contacts with continental cultures continued to increase in the Asuka. A wide range of political and cultural relations with the Korean kingdoms of Koguryŏ, Silla, and, in particular, Paekche provided an opportunity for comparatively systematic assimilation of vast amounts of Korean culture, Chinese culture read through a Korean prism, and the religious beliefs of Buddhism. It was within that period of intensive relations with Paekche that critical foundations were constructed for a radical shift in the direction of Japanese visual arts.

Introduction of Buddhism

The most significant change, of course, was the introduction of Buddhism. Historians debate the actual date of the arrival of Buddhist texts, implements of worship, and iconography in Japan, but according to tradition a Paekche delegation to the emperor Kimmei in 538 or 552 made the presentation of certain religious articles. Given the extent of contact with Korea, however, various "unofficial" introductions of Buddhism had probably already occurred. The religion soon found favour in Japan and flourished under the powerful regent Prince Shōtoku (574–622), who established it as the state religion.

Buddhism was already a thousand years old when it arrived in Japan. It had transformed and been transformed by the iconography and artistic styles of the various cultures along its path of expansion from India. The central message of Gautama Buddha (6th–5th centuries BC) had also experienced multiple interpretations, as evidenced by the numerous sectarian divisions in Buddhism. The artistic forms necessary to provide the proper environment for the practice of the religion were well defined, however—calligraphy, painting, sculpture, liturgical implements, and temple architecture—and these were the means by which nearly all continental modes of Buddhism were absorbed and adapted by the Japanese culture.

During this period of intensive peninsular contact, Korean artisans skilled in metalwork, sculpture, painting, ceramics, and other fields necessary to the production of Buddhist iconography immigrated to or were brought to Japan in large numbers. While the practice of most of the above-mentioned forms was the purview of professionals, the calligraphic rendering of the written word was a skill available to the educated elite of the period. Thus, in the Asuka period the foundations of both individualized and public forms of visual expression were secured.

Architecture. Buddhism was established in Japan as a site-oriented faith. Temples with designs initially based on continental models became centres of worship. In contrast to the importance of funerary art in the Kofun period, the artistic expression of the Asuka period was developed within the matrix of public and privately commissioned temples. By the close of the Asuka period in the mid-7th century, nearly all vestiges of tomb burial customs were actually outlawed as the new faith made extensive inroads.

The most important temple complexes of the period are the Shitennō Temple at Ōsaka, the Wakakusa Temple near Nara (both constructed by Prince Shōtoku), and the Asuka Temple at Asuka. All three are known only through archaeological remains, although Wakakusa, Shōtoku's private temple, which was destroyed by fire in 670, was reincarnated as the Hōryū Temple (see below). These temple complexes replicated forms popular in Paekche and Koguryŏ. They were walled compounds in which stood a second rectangular compound bordered by a continuous roofed corridor. This second enclosure was entered through a central gate on its south side and contained a variety of internal structures, such as a pagoda (a form derived from the Indian stupa that served the dual functions of cosmological diagram and reliquary of important personages) and a Golden Hall (*kondō*), both used for worship. Support buildings, such as lecture halls, a belfry, and living quarters, lay outside and to the north of the inner cloister. True to the continental style, the buildings and gates were sited along a south-north axis and were symmetrical in layout. It was within the various buildings, particularly the *kondō*, that sculptures representing various figures in the Buddhist pantheon were placed.

Asuka temple layout

Roof tiles, stone, and cryptomeria wood were the essential building materials, all indigenous or locally produced. Structures relied on the placement of vertical wood pillars secured on finished stone bases. Horizontal elements were added in varying degrees of complexity, and structural balance was based on the essential pillar concept.

Sculpture. While the structures of these temples did not survive, certain important sculptures did, and these images are generally associated with the name of Kuratsukuri Tori (also known as Tori Busshi). Tori was descended from a family of saddlemakers. Excellence in this trade required mastery of the component media of lacquer, leather, wood, and metal, each of which was, in various ways, also used in the production of sculpture.

A large, seated, gilt-bronze image of Shaka (the Japanese name for Śākyamuni Buddha, the historical Buddha) survives from the Asuka Temple and is dated to 606. Also extant is the gilt-bronze Shaka Triad of Hōryū Temple, which is dated by inscription to 623. The Asuka Buddha, heavily restored, is attributed to Tori based on the stylistic similarity of its undisturbed head to the renderings found in the Shaka Triad, which is confidently assigned to the master sculptor's hand. A more controversial work is a gilt bronze Yakushi (the healing Buddha), which carries an inscription of 607. It is very close to the style of Tori, but many date the work to the latter part of the century. The Triad and the Yakushi are now housed in Hōryū Temple. An inscribed dedication found on the halo of the central figure of the Triad suggests that the ensemble was dedicated to the recently deceased Shōtoku and his consort. A stylistically related work is the wooden statue of the bodhisattva Kuze Kannon in the Yumedono ("Hall of Dreams") of the Hōryū Temple. The Tori style seen in these works reveals an interpretive dependence on Chinese Buddhist sculpture of the Northern Wei dynasty (386–534/535), such as that found in the cave sites at Lungmen. Symmetry, a highly stylized linear treatment of draped garments, and a reserved and gentle facial expression with a characteristic archaic smile are the prominent distinguishing features of this sculpture. The Japanese interpretations in bronze and wood advance the frontally focused Chinese relief sculptures by beginning to suggest more fully rounded figures.

Tori style

Shaka Triad by Tori, comprising the Buddha Śākyamuni and a pair of bodhisattvas, bronze, 623, Asuka period. In the *kondō* of the Hōryū Temple, Nara. Heights of figures: (left) 92 cm, (centre) 86.4 cm, (right) 93.9 cm.

Asuka-En

Painting. Buddhist temples were decorated not only with sculpture but also with religious paintings, tapestries, and other objects. Most such works from the Asuka period have not survived. An exception is the Tamamushi Shrine, which consists of a miniature *kondō* affixed to a rectangular pedestal or base. This assemblage of wood, metal, and lacquer provides an excellent view of what a *kondō* of the period may have looked like and, perhaps more important, is decorated with the only known painting from the Asuka period. The painting program on the miniature *kondō* seems to depict, through images on various panels and doors, the deities normally found in sculptural form within the hall. Paintings on the panels of the base show aspects of Buddhist cosmology and scenes from jataka tales, those narratives that tell of exemplary incidents in the previous incarnations of the Buddha. Perhaps best known is the jataka of the Hungry Tigress, in which the Buddha prior to enlightenment chances upon a tigress and her cubs starving in a desolate ravine and offers his own body to them. The painting depicts a sequential narrative in one panel, showing the saint removing his robe, leaping from a cliff, and being eaten by the tigers. The painting style suggests an Indian prototype vastly influenced by the fluid linearity of Chinese Wei styles.

Hakuhō period. In 645 Prince Nakono Ōe (later the emperor Tenji) and Nakatomi Kamatari (later Fujiwara Kamatari) led a successful coup and promulgated the Taika reforms, a series of edicts that significantly strengthened the control of the central government. Through successive regimes, some violently introduced, the structuring of a highly centralized government continued. A major feature of the centralization process was the incorporation

and use of Buddhism as an instrument of unification. The period was thus noted for a rapid expansion of Buddhism as aristocrats competed in the construction of temples. Increasing funds were allotted for the expansion of Buddhist temples and acquisition of the attendant iconography required for the expression of the faith.

The seat of government moved several times after the coup, but in 694 the court returned to the Asuka area and a plan to construct a permanent capital at Fujiwara was implemented. The capital was eventually moved again in 710 to Nara.

Art historians have given the name Hakuhō to the period beginning with the Taika reforms and ending with the imperial move to Nara. As noted, it overlaps with the Late Kofun period and is also sometimes referred to as the Late Asuka or Early Nara period.

Architecture. Four major temples, Asuka, Kawara, Kaikankai, and Yakushi, were already within the area of the planned capital site at Fujiwara. Of the four, only Yakushi Temple has survived, although not at Fujiwara but as an exact replica in Nara, constructed after the move of the capital in 710.

As an imperially commissioned temple, completed about 697, Yakushi had been very prominent at Fujiwara, and the relocated Yakushi Temple assumed equal importance when it was rebuilt at its new site (*c.* 730). Most recent evidence suggests that the Nara version of the temple was precisely faithful to the Fujiwara original and thus can be considered an example of late Hakuhō period temple design. Notable in its layout is the new prominence given to the *kondō* as a major structure; it is located in the centre of the compound flanked by two pagodas, which are afforded lesser importance than in earlier temple layouts. The *kondō* faced a large courtyard, and when its large central doors were opened, the assembled faithful were treated to an impressive view of the sacred images it housed. A unique feature of the Yakushi architecture is the use of the double-roof structure, in which a *mokoshi,* or roofed porch, was placed between two major stories.

Hakuhō temple layout

Despite Yakushi Temple's importance, Hōryū Temple, formerly Wakakusa, Prince Shōtoku's private temple, which was reconstructed about 680, remains the most significant extant repository of Asuka and Hakuhō art. By employing an asymmetrical layout, Hōryū differs dramatically from the axial-line layout of the major temples of the first half of the century. The gently tapering five-story pagoda and the wider, squatter *kondō* at Hōryū are placed adjacent to one another in the centre of the compound, their greatly varying sizes visually accommodated by an entry gate that is placed slightly off the central axis. This diversion from Chinese notions of balance became characteristic in many features of Japanese aesthetics.

Sculpture. With the exception of the Shaka Triad dedicated in 623 (noted above), sculpture at Hōryū Temple was created in a period from approximately 650 until 711. Sculpture created from the middle of the century begins to reflect the influence of the Chinese Northern Ch'i dynasty (550–577) styles. The highly linear features of Northern Wei sculpture are supplanted by works that have emerged from their origin in relief wall sculpture and stand in the round as stolid, columnar figures with slight attenuation at the waist. Noteworthy of this new style are the four guardian figures who stand sentry over the quadrants surrounding the Shaka Triad and the more delicate Kudara Kannon held in the Hōryū Temple treasure house. The drapery at the feet of these statues flares forward rather than to the sides as in earlier works, allowing for a heightened sense of volume. The sculptures are executed in indigenous wood with some traces of gold and polychromy still remaining.

At Chūgū Temple, near Hōryū and once the residence of Prince Shōtoku's mother, a wood-sculpted image of Miroku Bosatsu embodies many of the characteristic features of the Hakuhō period. The delicately meditative figure sits with one leg pendant, its foot supported on a lotus, and the other leg crossed. The rounded cheeks, arching eyebrows, slight disproportionate swelling of the upper torso, and soft modeling suggest innocent, almost childlike features.

Other sculptural works from the second half of the 7th century show increased mastery of a wide variety of materials, including clay, and adaptive uses of lacquer. At Hōryū Temple a group of sculptures constructed of clay over wood and metal structures is arrayed in four distinct tableaux on the first level of the pagoda. Completed in 711, they are technically works falling into the Nara period. However, their virtuosity suggests that the techniques employed had been mastered in the final years of the 7th century. The heightened sense of realism, the more expressive faces, and the more rounded, three-dimensional forms, particularly as seen in the north-side tableau of the death of Shaka, suggest an assimilation of Chinese T'ang dynasty (618–907) style.

The Yakushi Triad

The cast-bronze statues in the Yakushi Temple are among the finest examples of Japanese sculpture extant. Known as the Yakushi Triad, the work consists of the

Nucleus of the Hōryū Temple, Nara. Founded in 607 during the Asuka period by Prince Shōtoku, the temple complex was destroyed by fire in 670 and rebuilt with a new layout in the Hakuhō period. In the courtyard are (upper left) the pagoda and (centre) *kondō* (Golden Hall), which houses the most sacred of the temple images.

By courtesy of the International Society for Educational Information, Tokyo

seated Yakushi Buddha flanked by the standing attendants Nikkō (bodhisattva of the Sun) and Gakkō (bodhisattva of the Moon). It is unclear whether these sculptures were produced after the temple's relocation to Nara or if they were transported from the original site. Literary evidence from the 11th century suggests the latter hypothesis, however, and these striking works are consistent with the confident, fleshy, idealized figures of the early T'ang period.

Painting. The finest examples of late 7th-century painting are found in the *kondō* at Hōryū Temple. Many of these wall paintings were irreparably damaged by fire in 1949, but photos and reproductions remain. One fresco depicting an Amida Triad shows graceful figures rendered with comparative naturalism and defined with consistent, unmodulated brush lines known as "wire lines" (*tessenbyō*). Like the Hōryū pagoda sculptures, the wall paintings suggest the influence of T'ang style.

Bodhisattva, detail from the Amida Triad, one of a series of frescoes in the *kondō* (Golden Hall) of Hōryū Temple, *c.* 710, Hakuhō period. Most of the original paintings were destroyed by fire in 1949. In the Hōryū Temple Museum, Nara. Height 3 m.

Nara period. During the reign of the empress Gemmei (707–715) the site of the capital was moved to the northwest sector of the Nara Basin. The new capital was called Heijō-kyō and is known today as Nara. Overcrowding, the relative isolation of the Fujiwara capital, and what would prove to be a constant nemesis to the Japanese state, an overly powerful Buddhist establishment, were some of the main factors contributing to the move.

The Nara period (710–784), also known as the Tempyō period, marks the apex of concentrated Japanese efforts to emulate Chinese cultural and political models. The new capital city was modeled after the T'ang capital at Ch'ang-an (near modern Sian), and complex legal codifications (*ritsuryō*) based on the Chinese system established an idealized order of social relationships and obligations. Thus, a hierarchical society was established, in symbolic and real terms, with all power proceeding from the emperor. The integration of religion into this scheme fixed a properly understood relationship between spiritual and earthly authority. Secular authority ultimately drew its power from this relationship.

The first several decades of the 8th century were marked by power struggles, political intrigue, attempted coups, and epidemics. This generally unsettled and contentious atmosphere caused the emperor Shōmu (724–749) to press determinedly for strengthening the spiritual corrective that he perceived to be offered by Buddhism. In 741 he established the *kokubunji* system, building a monastery and a nunnery in each province, all under a central authority at Nara. In 743 he initiated the planning for construction of that central authority—the Tōdai Temple—and of its central image, a massive bronze statue of the Birushana Buddha, known as the Great Buddha (Daibutsu). Shōmu envisioned religion as a supportive and integrated power in the rule of the state, not as a private faith or as a parallel or contending force. His merging of church and state, however, later enabled the temples to acquire wealth and privilege and allowed Buddhist priests to interfere in secular affairs, eventually leading to a degeneration of the national administration.

Integration of Buddhism and imperial rule

The Chinese taxation system, which was first adopted in Japan during the Taika reforms and further promulgated by the *ritsuryō* system, was based on the principle of state ownership of land and a national appropriation of the rice crop. It was, from the beginning, an inappropriate fit for the realities of Japanese agriculture. By mid-century the growth of privately owned, tax-free estates had shrunk the tax base, and this, coupled with the extraordinary demands for expansion, temple building, and icon manufacture, placed great strain on the general population. The concluding decades of the century were characterized by attempts to regularize government expenditure and to control the power of the Buddhist clergy. In 784 the capital was transferred north to Nagaoka, just west of present-day Kyōto. This was a prelude to the establishment of the capital at Heian-kyō, now called Kyōto, in 794.

What was meant to have been perceived as the cultural expression of a powerful government intent on adapting the very finest elements of T'ang international style was actually an extreme attempt by a comparatively weak government to conjure power through symbolic gesture. Nevertheless, the push to establish Japan as at least equal in splendour to T'ang China in its celebrations of Buddhism and to mark Japan as the magnificent easternmost extension of the faith's expansion in Asia allowed for a halcyon period for the creation of Buddhist art. Virtually all aspects of T'ang culture were absorbed during this period. Indeed, because Buddhism was later suppressed in China and much of T'ang Buddhist iconography destroyed, extant Japanese art of the Nara period serves as the single best reminder, once removed, of what the Buddhist glories of T'ang China must have been.

The main monument to the Nara period is undoubtedly the huge Tōdai Temple complex with its colossal central image of the cast-bronze Great Buddha. The construction of the Great Buddha Hall (Daibutsuden) commenced in 745, and dedication ceremonies for the nearly 15-metre-high seated figure were held in 752. Only fragments of the original are extant; most of the present sculpture dates to a reconstruction in 1692, which nevertheless gives ample sense of the scale and ambitions of Emperor Shōmu.

The Great Buddha

Two important Nara temples predate the initiation of the Tōdai Temple project. Kōfuku and Hokkedō were both constructed in the Gekyō ("Outer Capital") area to the east of the imperial palace (this "outer" area is now where most extant Nara period sites are located), and their assorted extant iconography bears witness to the revolution in sculptural rendering that is a distinguishing feature of 8th-century Japanese art.

Architecture. Kōfuku, the titular temple of the powerful Fujiwara clan, originally was established as Yamashina Temple in the area of present-day Kyōto in the mid-7th century. It was relocated to Nara in 710 by clan leader Fujiwara Fuhito (659–720) and given the name Kōfuku. In scale and in assembled iconography, Kōfuku Temple reflected the de facto political control wielded by the Fujiwara. Kōfuku was conceived as a place of worship and of monastic learning and as a centre for providing social services (such as medical and charitable aid) to the general population. After Fuhito's death an octagonal memorial hall was constructed, similar to the Yumedono at Hōryū Temple. This distinctive architectural addition to the tem-

Great Buddha Hall (Daibutsuden) of the Tōdai Temple, Nara. The original building was completed in 752 during the Nara period; the present hall is a late 17th-century reconstruction.
Onon Press—SCALA—Art Resource

ple indicated a shift away from the use of a pagoda or stupa as a large reliquary or memorial structure.

Sculpture. Records indicate that an assembly of 27 sculptures featuring images of the Shaka, bodhisattvas, and other attendants was completed and installed in Kōfuku Temple in 734. Of this grouping, six of an original ten disciples and all eight of the Eight Classes of Beings (designated as protectors or guardians of Buddhism) are extant.

Hollow-core dry-lacquer sculpture

These works are superb examples of the hollow-core dry-lacquer technique (*dakkatsu kanshitsu*) of sculpture, which was developed in China and enjoyed a sudden florescence in the Nara period. The technique required the creation of a rough clay-sculpted model on a wooden armature. This form was then covered with successive layers of lacquer-soaked hemp, each of which had to be dry before the next could be applied. Next, the back of the sculpture was cut open, the clay broken out, and, if necessary, a fresh armature inserted. Final surface refinements and details were then added using a paste mix of lacquer, sawdust, flour, and ground incense. Pigments and gold leaf were used to colour the finished form. Some sources suggest that the use of the new technique was encouraged in Japan because the casting of the Great Buddha at Tōdai Temple caused a shortage of the copper needed for bronze production. In addition, lacquer had the advantages of durability, insect resistance, and light weight. Perhaps most importantly, this additive technique of sculpting offered a more easily managed range of plastic expression.

The other major site for important Nara period works preceding the construction of Tōdai Temple is Hokkedō, also known as Sangatsudō, located at the eastern edge of the Tōdai complex. At present a curious mélange of 16 sculptural works is found on the altar platform in the temple. A hollow-core lacquer sculpture of the Fukūken-jaku Kannon functions as the central image. It is flanked by two clay images of the bodhisattvas Gakkō and Nikkō (sometimes identified as the guardian deities Bonten and Taishakuten). Much smaller than the central image, they date to the mid-8th century and were probably not created for the position that they now occupy. They are closely related stylistically to four clay guardian figures found in the ordination hall at Tōdai. Treatment of facial features in each of these clay works is individualized and highly refined. The Gakkō and Nikkō demonstrate a reserved energy and force while the guardian figures are bravura performances of gesture and elegant posture, but all are excellent examples of the Japanese command of T'ang-style powerful, inspirited, idealized forms.

The "secret" image of Shūkongōjin (733), a guardian deity, is secluded in a cordoned space behind the Fukūken-jaku Kannon and presented for viewing only once a year. A clay sculpture with its original gold leaf and polychromy largely intact, the thunderbolt-wielding deity is approximately life-size. Modeled on Chinese statues of guardian generals, the Shūkongōjin is a formidable image of swirling power and force and is the best preserved of the Nara-period clay sculptures, which like their hollow lacquer counterparts were formed on armatures.

Sculpture of the later Nara period began to employ yet another variation of the lacquer technique, that of adding lacquered cloth over a carved wood core (*mokushin kanshitsu*). Paste techniques similar to those used for hollow-core lacquer sculpture enhanced the image, and some elements were occasionally constructed solely of lacquer disguised as wood. To alleviate splitting caused by expansion and contraction, the wood core was usually partially hollowed. The use of lacquered wood-core techniques may reflect an attempt to reduce the expense involved in previously described sculptural methods. It also indicated an increasing penchant for employing wood, an abundant natural resource.

Wood-core lacquer sculpture

The new technique may have been brought to Japan by Chinese artists accompanying the venerable Chinese monk Ganjin (Chinese: Chien-chen) (688–763), for whom Tōshōdai Temple (founded in 759) was constructed, by some accounts from a structure disassembled and moved from the imperial palace. Housed in Tōshōdai Temple are several works using the new wood-core lacquer technique, including a 534-centimetre-high, 11-headed, 1,000-armed Senju Kannon, as well as a hollow-core dry-lacquer sculpture of Ganjin and a Birushana Buddha of the same medium, both dating to about 760. The Ganjin sculpture is a particularly commanding work that embodies the authority and dignity of the aged, blind patriarch.

In addition to new construction techniques, sculpture of the late Nara period also shows a stylistic shift, probably imitating a continental trend, toward more mannered depictions of drapery and a more stolid, fleshy form, conveying a brooding feeling. Typical is the rendering of a tight-fitting garment at the thighs of a subject, with drapery elsewhere carved in evenly spaced, concentric waves. This style, *hompa-shiki,* came to greater prominence in the early Heian period.

Painting. Painting of the period emulated T'ang prototypes. Noteworthy is an image of the deity Kichijōten, housed in Yakushi Temple. This work on hemp depicts in full polychromy a full-cheeked beauty in the high T'ang style, which was characterized by slightly elongated, pleasantly rounded figures rendered with long curvilinear brushstrokes. A horizontal narrative scroll painting, *Kako genzai inga kyō* ("Sutra of Cause and Effect"), depicts in crisp primary pigments and a naive, almost childlike style

events in the life of the historical Shaka Buddha as well as various incidents in his previous incarnations. This work features painting on the upper register and explanatory text beneath. It stands at the head of a particularly fruitful tradition in Japanese painting types.

Shōsō-in treasure house

Decorative arts. Located within the Tōdai complex, to the northwest of the Great Buddha Hall, is the Shōsō-in treasure house, an imperial storage house constructed shortly after the death of Emperor Shōmu in 756. The joined-log structure, built of cypress timbers that are triangular in cross section, resembles a granary, a style of construction known as *azekura-zukuri.* It houses an accumulation of imperial objects as well as gifts received at the dedication of the Great Buddha and later donated by Emperor Shōmu's consort, Empress Kōmyō. Additional articles were added to the collection in the middle of the Heian period (794–1185). The core group donated by Empress Kōmyō totaled about 600 objects, including calligraphy, paintings, religious ritual implements, samples of medicines, mirrors, lacquerware, and masks. The objects received as gifts at the dedication of the Great Buddha have origins as distant as the Mediterranean basin. Most of the objects seem to be of Japanese origin, but they reflect a range of T'ang period styles, and they provide a vivid picture of T'ang and Nara decorative arts.

One of the few decorative art forms not well represented in the Shōsō-in treasure house is ceramics. Nara period ceramics, like the other arts, were imitations and adaptations of T'ang styles. Of note was the production of wares covered with a lead glaze of the T'ang *san ts'ai,* or three-colour, type (green, brown, and yellow), a two-colour type (green and white), and a monochrome green.

Heian period. In 784 the emperor Kammu (737–806) relocated the seat of government to Nagaoka, a site to the north of Nara and slightly to the west of present-day Kyōto. This move was an attempt to escape the meddling dominance of the Buddhist clerics in Nara and thus to allow unfettered development of a centralized government. Nagaoka was marred by contention and assassination, however, rendering it an inauspicious location for the capital. Thus, in 794 a site to the east of Nagaoka on a plain sheltered on the west, north, and east by mountains and intersected by ample north-south rivers was judged appropriate by geomancers. Named Heian-kyō ("Capital of Peace and Tranquility") and later known as Kyōto, this city was modeled on the grid pattern of the T'ang Chinese capital at Ch'ang-an. Heian-kyō remained the site of the imperial residence, if not the consistent seat of political power, until 1868.

Florescence of Japanese art

For nearly four centuries Heian-kyō was the crucible for a remarkable florescence of Japanese art. Within a century after the move from Nara, political chaos in China caused the cessation of official embassies to the continent. Free from the overwhelming dominance of Chinese artistic models, Japanese culture, particularly literature and the visual arts, was able to evolve along independent lines and reflect national concerns. These developments were invigorated through dedicated aristocratic patronage of both religious art and a nascent secular art.

Although sometimes viewed nostalgically as an unbroken series of halcyon years during which courtly aestheticism produced the "classical" body of Japanese literature and art, the Heian period was, in fact, a time of on-going political contention during which imperial attempts at centralization of government were consistently checked and ultimately defeated by powerful provincial warlords. In theory, all land and its revenue-producing capability was the property of the central government. In reality, outlying land managers, aristocrats, temples, and warlords accumulated landholdings unabated throughout the Heian period, ultimately crippling the economic power of the court. In the waning years of the 12th century, internal strife over succession and a scramble for what wealth remained in imperial hands forced the court to restore order with the assistance of the warrior class. This steady decline in aristocratic fortune and power was perceived by courtiers as an impending collapse of a natural and just order.

Literature and art of the period were thus often infused with nuances of sadness, melancholy, and regret. The consolations of Buddhism stressed the impermanence of life and served to reinforce for aristocratic believers the deeper meaning of readily apparent social developments. Indeed the shifting emphases found in Buddhist iconography during the Heian period are incomprehensible unless viewed in the context of doctrinal responses to social change. Most significant among these are the establishment of two Japanese schools of Esoteric Buddhism, Tendai and Shingon, in the early 9th century, the increasing appeal of Amidism in the 10th century, and, with the understanding that Buddhism entered a final millenarian era in the mid-11th century, a florescence of various iconography produced in the hopes of gaining religious merit.

Esoteric Buddhism. The court in Heian-kyō was justifiably wary of Buddhism, at least in any powerfully institutionalized form. Thus, in the configuration of the new capital, only two Buddhist temples were allowed within the boundaries of the city. Tō Temple and Sai Temple, located respectively at the east and west side of Rashomon, the southern gateway to Heian-kyō, were conceded space that was as far away as possible from the imperial palace and government offices in the north of the capital.

Dissatisfaction with the scholastic Buddhism of the Nara sects was also voiced by some clerics. An imperially approved embassy to China in 804 included the well-known monk Saichō (767–822) and the lesser-known Kūkai (774–835). Saichō studied the teachings of the T'ien-t'ai sect (Japanese: Tendai), which emphasized the impermanence of all things, an ultimate reality beyond conceptualization, and a fundamental unity of things. Meditational practices were believed to lead to enlightenment. The *Lotus Sutra* (Japanese: *Myōhō renge kyō*) was regarded as the primary text of the sect. Saichō returned to Japan in 805 and petitioned the court to establish a Tendai monastery on Mount Hiei overlooking Heian-kyō. His request was granted, but the emperor required Saichō to include some Esoteric practices in his Tendai system.

Saichō and Kūkai

Kūkai devoted himself to the mastery of the relatively new Esoteric Buddhist beliefs under the Chinese master Hui-kuo. Returning to Japan in 806, more than a year after Saichō (who regarded Esoteric teachings as an aspect of the more inclusive Tendai tradition), Kūkai was welcomed as an Esoteric master. Through the force of his personality and the attraction of his teachings, he eclipsed Saichō in popularity. Whatever particular differences are found between Tendai and Shingon, as Kūkai's syncretic doctrine is called, the two schools are grouped under the central category of *mikkyō,* or Esoteric Buddhism. Neither belief system, as interpreted in Japan, rigorously emulated the Chinese versions; they were syntheses created by Saichō and Kūkai.

Use of mandalas

Esoteric Buddhism relied heavily on visualization in its praxis. The creation of an environment of worship was essential. The use of mandalas, expressed both in two dimensions as paintings and in three dimensions as ensembles of sculpture, invited the believer into a diagrammatic rendering of a spiritual cosmos. A central tenet of Esoteric teaching was the nonduality of the Buddha. Whatever the manifestations, the phenomenal and the transcendental are the same. The goal of spiritual practice was to unite what seemed to the uninitiated to be separate realms. Thus, one of the most important iconographic images was the *ryōkai mandara* ("mandala of the two worlds"), which consisted of two parts—the *kongō-kai* ("diamond world") and the *taizō-kai* ("womb world")—that organized the Buddhist divinities and their relationships in a prescribed gridlike configuration. The deities or spiritual entities portrayed in these paired paintings represent, in the *kongō-kai,* the realm of transcendant, clear enlightenment and, in the *taizō-kai,* the humane, compassionate aspects of the Buddha. It was the repetitive meditative practice of journey through and visceral assimilation of this symbolic, schematic cosmos that could lead the believer to an enlightenment of unity.

In 823 Kūkai was granted imperial permission to take over the leadership of Tō Temple (also known as Kyōōgokoku Temple), at Heian-kyō's southern entrance. Images developed under his instruction probably included forerunners of the particular *ryōkai mandara* known as the

Tō Temple mandala. Stylistically, these paintings reveal a shift from T'ang painting style to a flatter, more decorative approach to image. Also in the sanctuary at Tō Temple is an important assemblage of sculpture that constitutes a three-dimensional mandala. In a tandem similar to the one effected in mandala painting, dual aspects of the single Buddha nature are portrayed. Bodhisattvas represent limitless compassion, while other assemblages portray yet another dimension of the central divinity, one that came to heightened prominence in Shingon practice, the fierce Myō-ō, or Kings of Bright Wisdom. These manifestations, perhaps best typified by Fudō Myō-ō, are terrifying and uncompromising guides for the believer in the journey to enlightenment. To the unfamiliar eye, their appearance seems demonic, but their wrath is directed at the enemies of Buddhism. They extend to a more fantastic perceptual level the role of guardian general deities and offer a realistic assessment of the intensity of dedication needed for enlightenment.

In general, sculpture produced in the 9th and 10th centuries followed and developed from the techniques of the late Nara period. Many works were constructed using variations of the lacquered wood-core technique. The heightened mannerism and heavy, brooding quality noticeable in some late Nara works are found in abundance in the early Heian period. The great late 8th-century standing Yakushi figure housed at Jingo Temple north of Kyōto perhaps best typifies this style. Other fine examples can be found in Murō Temple, a well-known Esoteric sanctuary to the east of Nara. Stylistically, these works hearken back to a type of sandalwood sculpture that enjoyed popularity in India and in China. With occasional elaborations through the use of lacquer, these powerful works were essentially carved from large, single pieces of wood, a technique called *ichiboku-zukuri*. It has been suggested that Buddhist reformers planned the contrast between the abrupt, extreme force of these sculptures and the aristocratic elegance of Nara period works. Created unabashedly of wood, they represented the elemental force of the forests that surrounded the urban centres.

Single-block wood sculpture

Because Esoteric practitioners were initially relegated to the mountainous regions outside the capital, the layouts and architecture of their temples varied greatly from the flatland architecture of the Nara temples and, thus, from the symmetrical Chinese styles. Placement and structure were adapted to rugged terrain, creating unique solutions. Ironically, this relative individualism of style was a subtle symbolic disruption of Nara period attempts at a hierarchically dispersed power through visual means.

The highly syncretic nature of Esoteric Buddhism considered the noumenal aspects of indigenous religions as emanations or manifestations of the Buddha essence. Rather than confronting and competing with native deities and belief systems, *mikkyō* readily adapted and included their features. For example, Shintō, the primary indigenous religion, which had developed from ancient animistic cults, had a very limited iconographic program. Until the Heian period, Shintō deities (*kami*) were largely considered to be unseen, often formless spirits that inhabited or personified such natural phenomena as the sky, mountains, and waterfalls. Esoteric Buddhism, however, encouraged the inclusion of Shintō deities in a kind of subordinate tandem with Buddhist deities in a variety of visual representations. This incorporation of Shintō *kami* not only served as an acknowledgment of indigenous beliefs but also increased the thematic scope of Buddhist art, particularly landscape painting. The Shintō belief that topography and its included features of rivers, trees, and distinctive rock formations were the abodes of the spirits meant that a sacred formation of mountains could be interpreted as a topographic mandala. Rendering these forms in painting expanded the iconographer's repertoire beyond the production of anthropomorphized deities. This theory in which *kami* are viewed as temporary manifestations of the essential Buddha, allowing each Shintō deity to be identified with a Buddhist one, is known as *honji-suijaku*.

Honji-suijaku

Amidism. Devotion to Amida Buddha, who presided over the Western Paradise, or Pure Land, began in Japan within the *mikkyō* sects, and in the 10th century Amida worship began to gain momentum as a distinct form of Japanese Buddhist belief.

Like Esoteric Buddhism, Amidism encouraged an iconography that formed a total ambience of worship. The focus of faith in Amida was rebirth in the Western Paradise. Therefore, painted and sculpted representations of that celestial realm were produced as objects of consolation. Paintings from the Nara period of the Amida and his Western Paradise are geometrically ordered descriptions of a hierarchical world in which Amida is enthroned as a ruler. In mid-Heian Amidist images, the once-ancillary image of the descending Amida takes on central prominence. This image of the Amida Buddha and attendants descending from the heavens to greet the soul of the dying believer is called a *raigōzu* ("image of coming to greet"). The theme would later be developed during the Kamakura period as an immensely popular icon, but it saw its first powerful expressions during the Heian period in the late 11th century. As is typical of Amidism, the compassionate attitude of the divinity superceded expressions of awesome might. Amidism differed significantly in emphasis from Esoteric Buddhism in that it did not require a guided initiation into mysteries. An expression of faith in the Amida Buddha through the invocation of his name in the *nembutsu* prayer was the single requirement for salvation. Iconography served mainly as a reminder of the coming consolations rather than as the tool for a meditative journey to enlightenment.

Raigō images

One of the most elegant monuments to Amidist faith is the Phoenix Hall (Hōō-dō) at the Byōdō Temple in Uji, located on the Uji River to the southeast of Kyōto. Originally used as a villa by the Fujiwara family, this summer retreat was converted to a temple by Fujiwara Yorimichi (990–1074) in 1053. The architecture of the building, including the style and configuration of its interior iconography, was intended to suggest a massive expression of *raigō* imagery, whether viewed by a worshiper within the sanctuary or by a visitor approaching the complex from a distance. Viewed frontally, the hall resembles a large bird with its wings extended as if in landing, recalling the downward flight of the Amida and bodhisattvas who welcome the faithful. Contained in the breast of this great creature is the sanctuary, where a magnificent Amida sculpture by Jōchō (d. 1057), the premier sculptor of the period, rests on a central altar. Positioned on the surrounding walls is an array of smaller wood-sculpted *apsaras* (heavenly nymphs) playing musical instruments and riding on stylized clouds. Traces of poorly preserved polychrome painting on the interior walls depict not only the expected *raigō* scene but also the gently rolling topography of central Japan, suggesting that the court-sponsored painting bureau had developed a strong indigenous expression which now supplanted Chinese models in religious iconography.

The Jōchō Amida sculpture, one of the most sublime expressions of Amidist belief, marks the ascendancy of a new style and technique in sculpting. Serene, unadorned, reserved yet powerfully comforting, this image is composed of numerous wood pieces that have been carved and hollowed, then joined together and surfaced with lacquered cloth and gold leaf. This joined-block construction technique (*yosegi-zukuri*) allowed for a sculpture lighter in feeling and in fact, but it generally precluded the deep and dramatic carving found in single-block construction. Thus, the exaggerated, mannered presentations of Esoteric sculpture of the previous centuries were supplanted by a noble, evenly proportioned figure, and scale and calm mien replaced drama as a means to engage the believer.

Joined-block wood sculpture

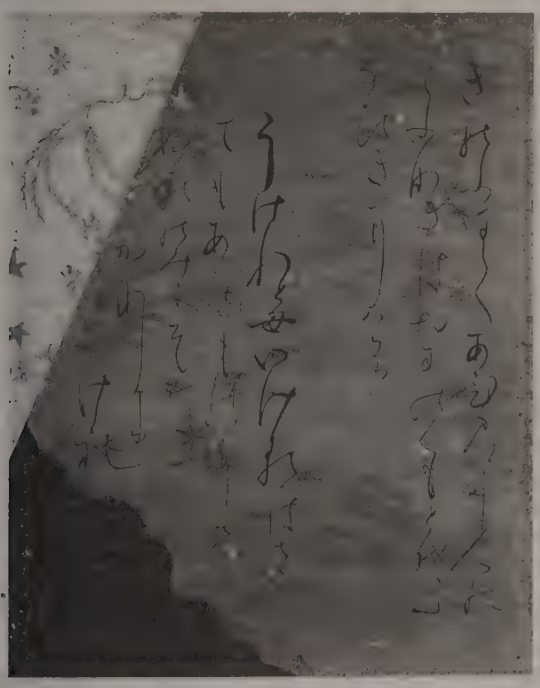
In 985 the Tendai monk Genshin (942–1017) produced the 10-part treatise *Ōjō Yōshū* ("Essentials of Salvation"), a major synthesis of Buddhist theory on the issues of suffering and reward and a pragmatic guide for believers who sought rebirth in the Western Paradise. Genshin described in compelling detail the cosmology of the six realms of existence of the Impure Land (*rokudō*) in an effort to encourage people to strive to achieve rebirth in the Pure Land of Amida. Genshin's descriptions of hell and its tortures were particularly influential as a source for artists in meeting a demand for graphic images of hell intended for meditation and instruction of the faithful.

Calligraphy and painting. The break in regular communication with China from the mid-9th century commenced a long period of fruitful development in Japanese literature and its expression through the mediums of calligraphy and painting. Calligraphy of the Nara period was known for its transmission and assimilation of the major Chinese writing styles, as well as for some forays into individualized expression and adaptation of technical features of character representation. Modified versions of Chinese characters, known as *man'yōgana,* were employed to represent Japanese phonetic sounds, and two even more abbreviated phonetic writing systems, *hiragana* and *katakana,* were known in nascent form. The former was highly stylized and cursive, while the latter was somewhat more severe and rectilinear in form. Use of *hiragana* was relegated to women, while men continued to control the learning and use of the traditional Chinese characters. However, during the Heian period *hiragana* was recognized as an official writing method, and an integrated use of the adapted Chinese characters (*kanji*) and *hiragana* became a widely accepted form of written expression.

The Buddhist monk Kūkai was an important calligraphic stylist and was posthumously recognized as the patron of calligraphers. His highly expressive and mannered presentation of characters was seen and admired in official correspondence, but, more significantly, he employed the brush in a spiritual exercise of rendering important sutra texts or single, meaning-laden *kanji*. These explorations functioned as part of an Esoteric rite that approximated use of a personalized mandala. Kūkai forcefully established the link between word and image embodied in a calligraphy text, and his work served as an important catalyst in the Heian period, when the rendering of a *kanji* or a phonetic symbol came to be appreciated not as an illustrative gesture but as a form of expression multivalent in its epistemological potential. In ensuing decades and centuries courtiers expanded on his work and explored the potentials suggested not just in a single character but in whole, secular texts, mainly poetry.

Importance of poetry

Contemporary documents discuss the relationship between poetry and painting. Poems were used as the subject of paintings, and calligraphers often wrote poems on paintings or on specially prepared square papers (*shikishi*) later affixed to a painting. Although virtually no examples of this custom survive from the Heian period, it is known through documentary sources and through revivals of the practice in subsequent centuries. Poetry was also inscribed on elaborately decorated sheets of paper which were preserved as individual units, consolidated in albums, or arranged on horizontal scrolls. The early 12th-century *Sanjūrokunin kashū* ("Anthologies of Thirty-Six Poets") is perhaps the finest Heian example of verse executed on sumptuously prepared and illustrated papers. The preeminence of the calligraphic word in interpretive union with painting or as a thematic inspiration for painting was a hallmark of the Heian period.



Page from the *Sanjūrokunin kashū* (known as the Ishiyama-gire), cursive *hiragana* script attributed to Fujiwara Sadanobu, early 12th century, Heian period. Panel-mounted album page, ink, silver and gold on assembled dyed paper. In the Freer Gallery of Art, 20.3 cm × 16.1 cm.

The Smithsonian Institution Freer Gallery of Art, Washington, D C

Changes in painting technique evident in the Heian period may well have been the result of the general and rapidly growing development of sophisticated calligraphic skills. The T'ang Chinese method of employing the even iron-wire brush line to delineate forms was gradually supplanted in the 11th century by subtle introductions of modulated, calligraphic brushwork, engendering greater liveliness in form, particularly in the renderings of such grand subjects as *raigō* and the Buddha's entry into nirvana.

Important secular works from the 11th century, such as *Shōtoku taishi eden* ("Illustrated Biography of Prince Shōtoku") and the Senzui folding screens (*byōbu*), also reveal the development of indigenous painting styles within the original interpretive matrix of Chinese forms. Although the Chinese method of representing narrative in a landscape setting is honoured, with each narrative episode shown in a discrete topographic pocket, the topography and other telling elements take on the appearance of Japanese rather than Chinese surroundings. By the end of the Heian period, a clear distinction could be made between paintings using Chinese themes and styles and those with Japanese subjects and techniques, with the former known as Kara-e and the latter as Yamato-e.

Kara-e and Yamato-e

Some of the most celebrated examples of Yamato-e are the horizontal narrative hand scrolls (*emaki* or *emaki-mono*) produced in the 12th century. This format, which had been introduced from China in the 6th or 7th century, had already been used effectively in Japan, most notably for the Nara period *Kako genzai inga kyō* ("Sutra of Cause and Effect"), but these early scrolls are thought to be imitative of Chinese works. In the Late Heian, however, *emaki* began to develop a unique Japanese character and proved to be particularly well suited to Japanese expression.

There are few extant narrative scrolls dating from the Heian period. Their quality is extraordinary, however, and probably representative of a larger number of works no longer extant. Typically, the format of presentation was that of alternating bodies of text and painting. The best of these works were not ploddingly literal in their visual interpretations of text. Rather they were carefully selective of their points of illustration, allowing maximum freedom to the viewer's imagination and demonstrating a complementary rather than repetitive use of text and image.

The range of expressive technique available to artists was considerable, and adaptation of style and composition to suit the tone of a narrative was, judging from available evidence, astute. *Genji monogatari emaki,* an illustrated narration of the late 10th- or early 11th-century court romance *Genji monogatari* (*The Tale of Genji*), was produced in the first half of the 12th century. The tale, which relates the life and loves of Prince Genji, is undergirded with Buddhist metaphysics and is thought to offer an approximate fictional description of court life at the time of its composition. It provides a complex analysis of emotions that are always obliquely expressed because of the constraints of court etiquette. The artists thus convey mood not with facial expression or gesticulation, which would violate the highly refined court aesthetic, but with formally posed figures rendered in opaque pigments and the skillful use of depicted architectural elements. Treatments of interior space subtly suggest the emotion masked by the human figures.

Genji monogatari emaki

Quite different from *The Tale of Genji* scroll is the 12th-century *Shigisan engi emaki* ("Legends of Shigisan Temple"). Drawing on folkloric sources, it is a tale of miracles attributed to the Shingon monk Myōren, who

resided on Mount Shigi near Nara in the latter part of the 9th century. The uninhibited depiction of action and movement central to various episodes is rendered by lively and varied brush strokes. Similarly, the first scrolls of the *Chōjū jinbutsu giga* ("Scrolls of Frolicking Animals and Humans"), products of the 12th century (later scrolls are dated to the 13th century), satirize human foibles through the depiction of anthropomorphized animals rendered in masterfully vibrant ink monochrome brushwork.

Detail of the *Chōjū jinbutsu giga* ("Scrolls of Frolicking Animals and Humans"), hand scroll attributed to Toba Sōjō, 12th century, Heian period. Ink on paper. In the Kōzan Temple, Kyōto.

The *Ban Dainagon ekotoba* ("Story of the Courtier Ban Dainagon") narrates the incidents surrounding the arson of a gate at the imperial palace in the mid-9th century. This work of the later 12th century is a masterful blend of technical styles. Movements of tension, suspense, thunderous action, and quiet intrigue are variously expressed by a combination of careful pictorial composition, adroit calligraphic technique suggesting action, and the use of opaque pigments to render pauses in the narrative.

The illustrated, or illuminated, sutra form, a type of *emaki,* reached its zenith of expression with the completion, in 1164, of the *Heike nōkyō*. This incomparable 34-scroll presentation of the *Lotus Sutra* with alternating text and painting was an offering of the military leader Taira Kiyomori (1118–1181).

Decorative arts. The kilns at Sanage to the east of present-day Nagoya provided functional ceramic pieces for the court. These were largely forms and glazes that were imitative of Chinese three-colour and celadon potteries, which used lead in their glazes. Lacquerware emerged as an art that provided a means of producing the effect of inlay work popular mainly as an import item during the Nara period.

The Kamakura period. From the middle of the 12th century the reality of true imperial court control over Japan was largely a fiction. The Taira (Heike), a provincial warrior family, assumed the role of imperial protector and became the effectual power wielder. From that time they entered into a protracted struggle for hegemony with the Minamoto (Genji), a powerful clan from eastern Japan. The Gempei War between the families raged through much of Japan's central island from 1180 to 1185, during which such major temples as Tōdai and Kōfuku and their contents were completely destroyed. The Minamoto eventually emerged victorious, and, under the leadership of Minamoto Yoritomo, the culture and structure of national leadership shifted from the civil aristocracy to the hands of a provincial warrior class. In 1192 Yoritomo was named *seii taishōgun* ("barbarian-quelling generalissimo") by the court, thus initiating an office of military dictator that would persist until the Meiji Restoration in 1868. Yoritomo located his power centre (later termed shogunate, or *bakufu,* literally "tent government") in Kamakura, a small seaside village on a peninsula to the south of present-day Tokyo. Control of the shogunate soon passed to the Hōjō family through Yoritomo's widow, but the government did not return to Kyōto until 1333. The years from 1185 to 1333 are thus known as the Kamakura period.

Rise of the warrior class

The military victory and subsequent structural changes not only established the new ruling group in a position of military and economic power but also allowed for the infusion and development of a new cultural ethos—one that paralleled but was determinedly distinct from that developed by the court in Nara and in Kyōto. Warrior values of strength, discipline, austerity, and immediacy found resonance in the practices of Zen Buddhism. This strain of Buddhism had long played a subsidiary role in Japan, but, from the 13th century, strong Japanese adherents were bolstered in number and authoritative leadership by immigrant Chinese monks who had been displaced by the Mongol conquests in China. Zen Buddhism offered the new military leadership a nonthreatening alternative to the Tendai-controlled religious establishment that dominated the Kyōto court. The iconographic needs and the inherent aesthetic predispositions of Zen Buddhism were refined through this initial relationship with the Kamakura elite and over the next several centuries became widely influential throughout Japan.

Populist religious movements, particularly those generated by Amidist beliefs during the Heian period, grew even stronger and more diverse during the Kamakura period, increasing demands for Buddhist iconography. During the 13th century fears of an invasion by the Mongols from the mainland were realized on two occasions (1274 and 1281). Both times the invaders were repulsed, but these episodes and their anticipation contributed to a pervasive anxiety that was more than occasionally exhibited in the mood and theme of religious iconography. It was a time punctuated by prayers of supplication and pleas for divine intervention. Although quite different in their fundamental precepts, the simple and direct means of access to salvation or enlightenment offered by Zen or Amidist practices were exceedingly popular.

Sculpture. Perhaps no single feature of the Kamakura period so exemplifies the unique character of the age as does the emergence of bold new sculptural styles. As a result of the widespread destruction wrought by the Gempei War, it was necessary to replace the extensive loss of religious sculpture. The most compelling works of the period were created in the 13th century, notably by the Kei family, led by Kōkei and his son Unkei. Inspired both by the exquisite idealism of the Nara-period works and by the fashion for realism found in Chinese Sung dynasty sculpture, the best of Kamakura-period sculpture conveyed intense corporeal presence. The style is frequently referred to as "Kamakura realism" but should not be confused with the notion of "realistic" in the sense of faithful rendering of the natural. While, for example, there is reference to careful anatomic understanding, this understanding is often rendered in extreme statement. The huge guardian figures created by Unkei and other Kei artists to flank the Nandai-mon ("Great South Gate") at Tōdai Temple are the epitome of this style. With bulging eyes, limbs lined with tributaries of protruding veins, and theatrical poses, these and similar works were direct and accessible to the mass of the Buddhist faithful.

"Kamakura realism"

In portraying a range of divine concerns from protection to sympathetic consolation, Kamakura sculpture responded to the spiritual climate of the age. The sculpture by Unkei's son Kōshō (d. 1237) of Kūya, the rugged old mendicant who advocated the unceasing repetition of the *nembutsu* prayer, is depicted realistically as determined and gnarly but with the fantastic grace note of a string of small Amida figures emerging from his mouth—a literal representation of his teaching. An exquisitely refined evocation of the protective and welcoming presence of the Amida is seen in the sculpture dated to 1269 and a product of the atelier of Kōshun. With its surface completely adorned with gold-leaf pattern cuttings (*kirikane*), this figure proclaims celestial splendour. The intensity of the deity's gaze, omniscient and direct, is accomplished by a Kamakura-period innovation: inlaid crystal eyes backed by white paper appropriately coloured to effect iris and pupil. For Kōfuku Temple, Unkei sustained the remarkable standards of the temple's renowned Nara-period hollow-lacquer sculpture with his production of figures such as the famous disciples of the Buddha, Muchaku and Seshin. The portrait sculpture of Muchaku conveys firm resolve, seasoned realism, and, thanks to subtle handling of fleshiness around the eyes, a hint of humour.

The finest of Kamakura-period sculpture is a seamless

union of meticulously crafted and assembled parts. While wood was the medium of choice, the dominant presence of a single tree, a feature characteristic of early Heian sculpture, is no longer present. The joined-block method was used with much greater frequency than in previous periods. Effects were achieved through the coordination of skills, and specialization within workshops was common. In some cases the face of a sculpture was worked separately, as if a mask, and then affixed to the sculpture. The refinement of this ability to work on individual parts allowed for remarkable detail and expressive effects, enhancing the meticulous realism characteristic of Kamakura sculpture.

New architectural styles

Architecture. New architectural styles also emerged from the void created by the Gempei War devastation. No person was more instrumental in the renaissance of religious art and architecture than the monk Shunjōbō Chōgen (1121–1206), who oversaw the restoration of Tōdai Temple. Nandai-mon, the main entry gate of this revered temple, offers a superb example of the *tenjiku-yō* ("Indian style," although it originated in Southern Sung China) of architecture introduced during the reconstruction. Extravagantly conceived eaves wing out more than 5 metres (16 feet), supported by nine-tier brackets. The simple mechanics of this operation lie exposed, straightforward and bold, like the overall impression of the gate's design. Far less refined than Heian architecture, the immediacy of the new, and comparatively short-lived, style typified the aesthetic directness of the age.

"White Path to the Western Paradise Across Two Rivers" hanging scroll, *c.* 1300, Kamakura period. Ink, gold and silver, and kirikane on silk. In the Cleveland Museum of Art, Ohio, U.S. 123.4 cm × 50.7 cm.

Similar simple lines were features of the newly introduced Chinese Ch'an (Japanese: Zen) religious architectural style, which included slightly more complex bracketing supports joining columns and horizontal elements. Prosaic elements such as dormitories and refectories were part of the central plan, thus uniting overall design scheme with the important realities of communal life. Meditation halls were also more prominent. On the whole, however, traditional architecture in the period tended toward the decorative and overworked, as nonessential elements multiplied and functional units were embellished. Oddly, where technical virtuosity served the sculptural format well, the necessary simplicity of monumental architecture was compromised by too much display.

Painting. Painting of the Kamakura period, both religious and secular, was marked by a sense of immediacy and vitality. The Amidist sects spawned cults that emphasized devotion to particular intercessory figures who had initially been considered ancillary in the overall Pure Land Buddhist pantheon. The popularity of Amidism also encouraged the creation of elaborately conceived spiritual cosmologies in paintings depicting the six realms of existence. In a variation of that theme, paintings of the Nika Byakudō ("White Path to the Western Paradise Across Two Rivers") type show both the difficulties encountered by the believer journeying to the Western Paradise and, at the centre, the bodhisattva Jizō benevolently ministering to those in need. Similarly, *raigō* paintings featuring depictions of the Amida and entourage descending from paradise to greet the souls of the recently deceased faithful enjoyed considerable popularity.

As was the case with sculptural representation, immediacy and accessibility were the most desired attributes of religious iconography. Religious foundations made extensive use of the narrative scroll format to honour sect anniversaries or histories and to document the biographies of founders and other major personalities. In vitality of defining brushwork, rich palette, and lavish depiction of the sundry details of contemporaneous existence, such works serve as essential records of the material culture of the Kamakura period; but in a more profound religious sense, they are visual evidence of the strong Japanese penchant for grounding the spiritual experience in the easily approachable guise of everyday life.

Zen Buddhist painting

The use of iconography in Zen Buddhism was not as extensive as in other sects, but mentor and patriarch portraiture played a significant role in the ritual of the transmission of teaching authority. Here, too, the penetrating effect of presence was the quality most sought in these visages. Ink monochrome painting was also employed by Zen adepts as a form of participatory spiritual exercise. In addition to representations of personages or historic moments, real or legendary, associated with Zen, Zen painters also depicted subjects not obviously religious in theme. Bird-and-flower paintings were created and queried for insights into spiritual meaning, and gradually the landscape painting offered accretions of symbolic meaning indicative of internal, spiritual journeys.

During the Kamakura period, Buddhism continued and strengthened systematic efforts to incorporate the indigenous religion, Shintō, by identifying local gods and numinous presences as manifestations of Buddhist deities. This system was called *honchi-suijaku,* and its principles were applied extensively. Religious paintings often depicted the figures of both Buddhist and Shintō manifestation in some mandala-like format. Likewise, Buddhist paintings, especially of the *honchi-suijaku* type, frequently incorporated Shintō sacred sites into their landscapes. Not precisely of this type, but a sublime derivative, is the icon of Nachi Falls. Here, a sacred site on the Kii Peninsula south of Ise reveals the haunting presence of the great, constantly plunging force which all but overwhelms the small architecture of the Shintō shrine that honours the natural site. Thus, certain Buddhist traditional painting techniques revealed the sacredness of adopted territory.

Secular painting

In the realm of secular painting, as in the religious world noted above, the narrative scroll continued to develop as an essential expressive format. The popularity of war tales, appropriate to the climate inspired by the interests of

"Nachi Falls," Shintō hanging scroll painting, 13th–14th century, Kamakura period. Colour on silk. In the Nezu Art Museum, Tokyo.

By courtesy of the Nezu Art Museum, Tokyo

the new national leadership and by the threat and reality of foreign invasion, is readily apparent in extant paintings commemorating various domestic martial episodes. Few paintings of the period capture the force, confusion, and terror of battle as effectively as does the episode of the burning of the Sanjō Palace in the *Heiji monogatari emaki*. Here, the artist uses highly animated, modulated strokes of defining ink, judicious, repetitive patterning, and the application of opaque colour to produce a series of carefully joined vignettes that intimately and actively tell the story.

The court, although stripped of political power, continued to be an arbiter of cultural matters. Most especially, it dominated the development of a national literature and the rendering of that literature in relation to painting and calligraphy. The various modes of joining word and image continued to be the specialized purview of aristocratic culture. In the early 13th century important anthologies were assembled of the works of the 36 ancient poets who had been "canonized" in the Heian period, and portraits of these masters were popular painting subjects. Often, the horizontal narrative scroll format was used to present the poets as if they were engaged in poetry competitions, composing linked verse (*renga*), with representative verse juxtaposed by their images. Thus, even the comparatively subdued ambience of court culture was animated by the format so attuned to the dynamism of the period. The 36-poet genre was thereafter a resilient theme and a standard way of expressing high literary reference in painting.

Secular portraiture saw developments stimulated in part by the central role of patriarch and mentor portraits in the Zen tradition. The schematic or generalized visages of the Heian-period indigenous traditions were influenced by these imported developments. Court and military portraits of the period tend to present the subject in the stiff, opaque, and decorative surrounding typical of Heian style, but faces are more realistically and individually rendered.

The Muromachi period. Ashikaga Takauji, a warrior commissioned by the Kamakura shogun to put down an attempt at imperial restoration in Kyōto, astutely surveyed circumstances and, during the years 1333 to 1336, transformed his role from that of insurrection queller to usurper of shogunal power. The Muromachi period (1338–1573) takes its name from a district in Kyōto where the new shogunal line of the Ashikaga family established its residence. With Takauji's ascendancy a split occurred in the imperial lineage. A southern court in exile formed in the Yoshino Mountains, to the south of Nara, while a court in residence, under the Ashikaga hand, ruled from Kyōto. This double regency continued until the end of the century, when a duplicitous compromise finally stripped the southern court of claims to power. This imperfectly resolved situation henceforth provided both political and romantic aesthetic evocations of legitimate power deposed. It became a rallying point for royalists and a continuing subtle undercurrent in literature and the visual arts, a metaphor for the contention between the brute force of arriviste pretensions and the sublime culture of legitimate rule. By extension, it harked back to the halcyon days of Heian court rule.

The Ashikaga family held relative control of national power until the mid-15th century, when other aggressive provincial warlords provoked a struggle that culminated in the Ōnin War (1467–77). This civil war laid ruin to much of Kyōto and was, in effect, the initial skirmish in a century of ongoing military conflict. Ashikaga men continued as figurehead rulers until 1573, when Oda Nobunaga dismissed the last Ashikaga shogun.

Military patronage of the arts

The military rulers attempted to establish their legitimacy through their patronage of the arts. They assiduously promoted Zen Buddhism and Chinese culture in opposition to the aristocratic preference for indigenous styles. The increase in trade with Ming China and the avid cultivation of things Chinese encouraged by the Ashikaga rulers established a dominant aesthetic mode for the period, and journeys of monk-artists to and from China provided yet another avenue for stimulation of the arts.

Meanwhile, Japanese court culture, using Heian-period aesthetic achievements as a canonical norm, continued to foster and develop indigenous visual forms. Both court and shogunal currents—what might be called, respectively, conservative and Sinophilic—were strengthened by interaction. While the various patronage groups were, to a degree, antagonistic, the juxtaposition generally stimulated experiment and challenged stagnant modes of visual representation.

In addition to the cultural changes wrought by sheer military power, the egalitarian structures of Zen Buddhism and other populist Buddhist movements provided the possibility of startlingly swift advancement and important patronage for talented but low-born individuals. Many found that the indeterminate social status afforded by religious ordination provided the means to move freely among different classes. It was also common to assume a religious status as a kind of social camouflage without the actual benefit of ordination. Artists of every sort found temple ateliers congenial to their talents in this time of relative meritocracy.

Zen Buddhism firmly established its role of intellectual leadership during the Muromachi period and provided a strong line of continuity with the aesthetic trends established during the Kamakura period. Growing in real power, the temples became to an even greater degree centres for the consideration, assimilation, and dissemination of continental culture.

Buddhism responded to the elevated cultural aspiration of its believers, clerics and laity alike, by providing occasions in which the realms of the aesthetic and religious were, in practice, joined. The development of the tea

ceremony, which became increasingly important because it linked heightened religious sensibility with artistic connoisseurship, is a prime example of Buddhism's role in fostering new art forms in this period.

Regional dissemination of central cultural values was another important catalyst for development. The increasing strength of provincial leaders allowed them to assume patronage roles and to invite distinguished Kyōto artists to regions distant from the centre of culture. From the time of the Ōnin War and in the century following, this process was accelerated as Kyōto was engulfed in martial conflict.

Painting and calligraphy. The most significant developments in Japanese painting during the Muromachi years involved the assimilation of the Chinese ink monochrome tradition, known in Japanese as *suiboku-ga* or *sumi-e*. Zen Buddhism was the principal conduit for knowledge of this painting tradition, which was originally understood as an exercise potentially leading to enlightenment, either through viewing or in the practice of putting brush to paper. It was practiced both by amateurs and by professional monk-painters in temple ateliers.

In about the year 1413 Josetsu, a monk-artist of the Ashikaga-supported Shōkoku Temple, was commissioned by Ashikaga Yoshimochi (1386–1428) to produce a painting in the "new style" (thought to be that of the Southern Sung). The resulting work shows a man with a gourd standing near a stream and a catfish swimming in the water. Originally mounted as a small screen, the painting was soon transferred to the hanging scroll format, and the poetic commentaries of 30 monks were appended to the painting. This is perhaps the most famous work by the artist, who—as the master of Shūbun (fl. 15th century), who, in turn, instructed Sesshū (1420–1506)—is generally considered to stand at the head of the most important lineage of Muromachi ink painters. Josetsu's work alludes to the shogun's dominance of the elemental and sometimes unpredictable forces of nature and society, which are represented by the wily catfish. It can be understood as an instruction in the limitations of and deluded aspirations for power. It also suggests a style of Zen pedagogy in which a visual or verbal puzzle (in this case, how does one catch a slippery catfish with a small gourd?) prompts a dialogue between master and pupil as an exercise toward enlightenment. Noteworthy here is the fact of an exceptionally skilled painter operating well within the parameters of painting as religious exercise and also revealing the essential links between political power and Zen Buddhism's florescence.

Later, ink monochrome painters attempted themes that included Taoist and Buddhist patriarchal and mythical subjects, bird-and-flower compositions, and landscapes. It is instructive to note that in the course of the 15th century the progress of the three-generation lineage of Josetsu, Shūbun, and Sesshū can be described as a movement from physical permanence and relative security to a peripatetic existence necessitated by political instability and from conservative to more generalized or secular themes. Sesshū, who traveled to Ming China and was influenced by court painters, saw that Chinese painting was far greater in range than the ink monochrome tradition. His later works demonstrate a subtle use of colour and complex, seemingly random compositional formats, suggesting an increasing priority of brush stroke and patterning as the true subject. His long landscape scroll produced for the Mori clan in Yamaguchi is a brilliant study of boldly described forms in linear movement. He is also known for his landscapes in the *haboku* ("splashed-ink") technique, a style promulgated by Chinese Ch'an Buddhist painters who likened the spontaneous brushwork and intuitively understood (rather than realistically depicted) forms to the spontaneous, intuitive experience of Ch'an enlightenment.

Ink painting was not only the province of Zen Buddhists. Painters of the Ami lineage (so called because they used the suffix "ami" in their names to indicate their faith in Amida) served the Ashikaga shoguns as aesthetic advisers.

Painters of the Ami lineage

"Viewing a Waterfall," hanging scroll by Geiami, 1480, Muromachi period. Ink and colour on paper. In the Nezu Art Museum, Tokyo. 106 cm × 30.3 cm.

They graded and organized the shogunal collections of Chinese art and, as practitioners of the ink monochrome form, tended to a more gentle, polished conservatism than the bold, rough brushwork of the Shōkoku Temple painters. This tendency is seen in a work by Geiami (1431–85) painted on the occasion (*c.* 1480) of the departure of his pupil Kenkō Shōkei. It depicts the common subject of travelers passing beyond a turbulent pool and plunging waterfall to a temporary shelter nestled in a grotto. The sentiment is clear, and the execution reveals a mannered, controlled hand. The standard representation of receding far distance is suggested, but, in comparison with Chinese and earlier Japanese works, the balance of the painting is now subtly disrupted and the frontal plane becomes the focus of the work.

Sesson Shūkei (1504–*c.* 1589), another master of the ink monochrome format, was a mendicant with eclectic training. Eschewing any apprenticeship in Kyōto, he worked in a style charged with highly individualistic energy that captured the brooding uncertainties of the warring period.

The late Muromachi transition to secularization of the ink monochrome format is best expressed in the work of Kanō Motonobu (1476–1559). His father, Masanobu (1434–1530), stands at the head of a lineage that became, in following centuries, the dominant Japanese painting academy. The Kanō group was one of several important ateliers to develop important syntheses of Chinese and indigenous painting styles. Motonobu married into the Tosa family of Yamato-e painters, symbolically and literally effecting this gradual eclecticism. His sliding door panel paintings for Daitoku Temple in Kyōto depict famous episodes of Zen enlightenment. High professionalism, delicate coloration, and a skillful narrative instinct are apparent in this sweeping composition.

Although ink monochrome painting reached its height in Japan during the Muromachi period, other painting styles also flourished. Polychrome depictions of the patriarch reveal a consummate skill in execution. The eccentric visages of the disciples of the Buddha are found in a set attributed to the painter Ryōzen. They not only convey the persistent Zen fascination with spiritual force found in personality but also contain lush patterning and detail, as if a rugged eremitic type is slowly being enveloped in indigenous interests. These works, it should be said, also reflect dependence on Sung Chinese interpretations.

The indigenous Yamato-e tradition also continued to develop during this period. The polished narrative painting forms found in the late Heian and Kamakura periods were still produced but were eclipsed by styles that conveyed energy at the expense of surface refinement. Their genesis paralleled the growth of narrative literature, which treated a growing number of legends and folktales. Also appearing with greater frequency was a narrative compositional technique that mixed word and image by juxtaposing text closely to the figure speaking the words, almost in cartoon style.

Narrative painting

Screen painting in a rich polychromatic style persisted in parallel to the sparser, more obviously intellectual monochromes of the Zen tradition. The best of the Muromachi Yamato-e style screens show, in material and in sensibility, influences of metalworking, lacquering, and textile crafts. These works convey the reality of pragmatic creativity, which would come to full flower at the close of the 16th century.

The trends in Japanese calligraphy continued in essentially two major channels—the court-inspired, elegantly mannered script and the bold, ruggedly expressive forms of the Zen tradition.

Ceramics. The Muromachi-period taste in ceramics was, like painting, massively influenced by Chinese and Korean taste. Celadon ware was imported in large quantities. Known in Japan as Tenryūji ware, this light green monochrome ware was produced in many shapes as service ware and can be seen depicted in various narrative paintings of the period. It was imported as part of a large trading scheme managed by the Zen Tenryū Temple to support its works. Shogunal taste also favoured the sparse, darker ceramics from China, including *temmoku* ware, which revealed beautiful random effects in glaze colouring.

These comparatively austere Chinese ceramic types were gradually understood to have potential native equivalents in the ruggedly simple storage jars produced in Japanese kilns. Finely controlled glazes and enamel polychromy, which required the use of kaolin clay and controlled high firing, were still technically beyond Japanese capabilities; but the high regard in which the elegantly simple Chinese ware was held caused connoisseurs to elevate the status of once humble works and to commission Japanese interpretations of continental ware in Japanese kilns.

Lacquerware. Similarly, the appreciation of lacquerware was stimulated by the importation of fine Chinese works. The carved lacquer technique developed in Yüan China was emulated in a somewhat simpler manner in Japan. Lacquerware of a subdued red and black palette, said to have originated in the workshops of the Negoro Temple to the southeast of Ōsaka, was favoured in Buddhist establishments for its worn, unaffected look.

The tea ceremony. Perhaps the most calculatedly effective aesthetic development of the Muromachi period was the emergence of the cult of tea. The environment gradually required for tea gatherings grew into a kind of ritualized theatre in which objects removed from their original contexts were offered as worthy of consideration both in and of themselves and as metaphors for religious or philosophical perspectives. Zen monks imported tea plants from China, where the beverage was used for its medicinal qualities and as a stimulant in meditation. They also participated in a simple ceremony of consumption that included the use of certain prescribed utensils and implements.

From these fairly simple origins as a moment of respite and spiritual conviviality, the tea ceremony grew in complexity. Tea competitions (*tocha*) with the goal of discerning various blends began to be held in the Muromachi period and were espoused by Murata Shukō (*c.* 1422–1502), who was a disciple of the Zen master and abbot Ikkyū and is traditionally credited with founding the tea ceremony in Japan. An aesthetic adviser to the shogun Ashikaga Yoshimasa, Shukō prepared tea for his master at the latter's villa Ginkaku ("Silver Pavilion," now a temple) in a separate structure with a small tea room called

Founder of the tea ceremony

the Dōjinsai. Shukō and those in his circle stressed the spiritual elements of the ceremony and encouraged the display of a piece of Zen calligraphy at the ceremony.

About this time the size of the tea ceremony room was standardized to four and a half tatami mats. Shelving, a recessed wall element or alcove (tokonoma), and other features provided places for displaying art appropriate to a season, mood, or other occasional intention. Implements such as tea cups, water jars, and kettles were carefully choreographed for the occasion.

The codification of the ceremony developed through the late Muromachi period and flowered in the succeeding Momoyama period. Similarly, the aesthetic intentions were more carefully articulated with time. In general, these goals included the cultivation of simplicity and the appreciation of rusticity. Within the careful ritual of tea preparation and sharing, the proper blend of object and participants was intended to heighten an awareness of transience and fragility. It trained the participant to be predisposed to learning from the simple and to seek new levels of meaning through the creative juxtaposition of objects, painting, and calligraphy. The practice of the tea ceremony had profound impact on the nature of fine art collecting by proposing new values for previously existing art and by encouraging the creation of works especially for use in the ceremony. In a time of radically shifting social alignments, it is noteworthy that the ambience of the tea ceremony thrived on suggested visual contrasts between the rustic and refined.

Architecture and garden design. The development of the tea ceremony encouraged architectural changes during the Muromachi period. The need for a small, discrete environment as a place of contemplation or connoisseurial consideration led to the evolution of both the tea room and a small study room, called *tsuke shoin,* containing a ledge used as a desk, shelves, and sliding shoji windows that opened onto an auspicious, usually man-made, view. The sprawling style of Heian-period construction, called *shinden-zukuri,* was modified to accommodate the reduced circumstances of the aesthete in the turbulent Muromachi period, and domestic architecture began to take on a more modest, carefully circumscribed, and mannered appearance.

The *shoin,* or study alcove

The consciousness of controlling an environment to produce effect was ever more evident and extended to the development of garden design. The various styles, whether dry or wet, presented a highly calculated series of meanderings and views. The prototypical aspiration of garden design was said to be an evocation of the environs of the Amida's Western Paradise.

Stately, symmetrical gardens, which reflected the ordered, aristocratic hierarchy and *shinden-zukuri* architectural style, are nowhere to be found in the Muromachi garden aesthetic. Retained from the tastes of previous periods was the penchant for blurring the line between created structure and nature; buildings were often constructed to be unpretentiously rustic, while gardens were meticulously designed to be viewed but not entered. Gardens were understood and meant to be read as a journey into a three-dimensional painting. The tea aesthetic was influential in their design. The careful reordering of nature in a "natural" way provided enlightened views for the careful observer. The hermitage and its natural surroundings became, in obviously mannered forms, an aesthetic touchstone for the times.

The Azuchi-Momoyama period. The brief span of time during which first Oda Nobunaga (1534–82) and then Toyotomi Hideyoshi (1536/37–98) began the process of unifying the warring provincial leaders under a central government is referred to as the Azuchi-Momoyama, or Momoyama, period.

The dating of the period is, like the name, somewhat relative. The initial date is often given as that of Nobunaga's entry into Kyōto in 1568 or as that of the expulsion of the last Ashikaga shogun, Yoshiaki, from Kyōto in 1573. The end of the period is sometimes dated to 1600, when Tokugawa Ieyasu's victory at Sekigahara established his hegemony; to 1603, when he became shogun; or to 1615, when he destroyed the Toyotomi family. It should be noted that the rigid application of an essentially political chronology to developments in the arts can be deceptive. Many important cultural figures were active not only during the Momoyama period but in the preceding Muromachi or succeeding Edo period as well. Similarly, artistic styles did not necessarily change with each change in political system.

Discrepancy between political and artistic periods

In any case, Nobunaga's rise is the referent event for the start of the period. He selected Azuchi, a town on the eastern shore of Lake Biwa, a few miles to the east of Kyōto, as the site of his new government. It was there that a purportedly magnificent castle (now known only through records) was constructed between 1576 and 1579 and destroyed shortly after Nobunaga's death. A product of military necessity as well as an extension of the bold and outsize personality of its resident, this innovative structure presented enormous decorative challenges and opportunities to Kanō Eitoku (1543–90), the premier painter of the period.

Nobunaga's successor, Toyotomi Hideyoshi, was, of the three hegemons of the period, perhaps the one most enthusiastically involved with the arts. He constructed several castles, including one at Momoyama, just to the south of Kyōto. The name Momoyama has since become associated, as has Azuchi, with the lavish and bold symbolizations of political power characteristic of the period.

The fact that the two castle sites lend their names to the era seems especially appropriate artistically because the castle was the single most important crucible for experimentation in the visual arts in the Azuchi-Momoyama period. The development of the castle also points up several salient features of the age: a display of massive power held by provincial warriors not previously noted for high cultural aspirations, growing confidence in national stability, and the conscription of artists to articulate the new mood.

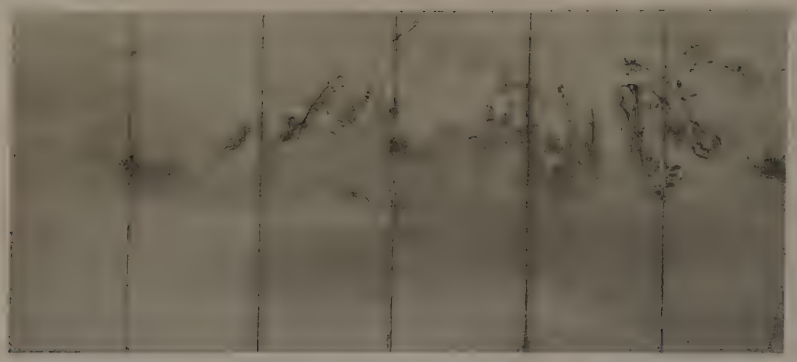
The development of the visual arts during this period was characterized by the vigorous patronage of two groups: the military leadership, who brought civil stability, and the merchant class, which formed the economic backbone of the revitalized urban centres. In addition, a much diminished aristocracy was still intent on retaining a hand in the arbitration of culture. Each group found not only genuine pleasure through their patronage of the arts but, in a time of major social realignments, legitimization and proclamation of their social status as well.

Architecture. The Japanese castle was a totally indigenous architectural form that developed in the 16th and early 17th centuries, a by-product of the hostile military conditions that existed in Japan from the time of the Ōnin War and in the following 100 years. Before that time military architecture had primarily consisted of small wooden fortresses; the earliest stone structure was probably constructed in the 1530s. Castle architecture experienced its florescence and most imaginative expression in the period from 1600 to 1615. In fact, most of the extant castles are products of that period. By 1615, however, each domain was allowed only one castle, and all other castles were ordered destroyed. Indeed, further castle building by the domain lords, or daimyo, was later banned. Continuing need for fortification would have implied either hostile intention or impending instability. Either suggestion was unacceptable to the Tokugawa rulers.

Castle layout

The general castle layout consisted of a donjon, or reinforced tower, called the *tenshu,* around which were arranged gardens, parks, and fortified buildings used for both official and private purposes. The whole was surrounded by deep moats and massive stone walls. Castle interiors presented a new dimension of decorative challenges. Large, generally dark spaces were subdivided by sliding panels (*fusuma*) and folding screens (*byōbu*). These two elements provided the format, depending on the wealth and predilection of the patron daimyo, for extensive painting programs. While architectural and religious iconographic needs of previous eras required paintings of considerable scale, the quantity, stylistic bravura, and thematic innovations of the Azuchi-Momoyama period are singular in the burst of confident national energy that they represent.

The *shoin* style noted first in the Muromachi period continued to be refined. A veranda linked the interior of most



"Pine and Camellias," one of a pair of six-panel screens attributed to Kaihō Yūshō, late 16th–early 17th century, Azuchi-Momoyama period. Ink, colour, and gold on paper. In the Cleveland Museum of Art. 157 × 358.4 cm.

structures with the carefully arranged, highly cultivated exterior gardens. An interior room with shelving and a tokonoma for the display of a hanging scroll of painting or calligraphy continued to be the primary showroom for fine arts, although *fusuma* and *byōbu* decorated with large-scale paintings could be found throughout the structure. The main room was often divided into two levels, the slightly raised one, which was backed by the tokonoma and fronted by decorative wood carving, being reserved for the highest-ranking person present. Unlike the *shinden* style, which used curtains and folding screens to partition small areas of a single large room, *shoin*-style structures were divided into several rooms by fixed walls and sliding doors. With variations in scale, this was also true for the architecture of religious establishments.

Painting. Painting was the visual art form that offered the most varied opportunities in the new age and, in fact, the most notable area of achievement. A breakdown of the comparatively rigid lines that had previously defined the various painting styles began in the Muromachi period and continued in the Momoyama. The Kanō school developed two distinctive styles: one featuring bright, opaque colours on gold or silver backgrounds, brilliantly amalgamating bright colour and bold brushwork, and the other a more freehanded, mannered, and bold interpretation of traditional ink monochrome themes. Other schools varied these two styles into distinctive lineage voices, but the Kanō group under Eitoku dominated the period through sheer talent and by amassing important commissions.

The Kanō school

At Eitoku's death several other figures who had worked either in secondary collaboration or in competition with the Kanō atelier emerged as strong individualist painters. Kaihō Yūshō (1533–1615) probably trained in the Kanō studio, but his independent style, most characteristically revealed in richly nuanced ink monochrome on gold or silver background, owed much to a careful study of Zen painting. Hasegawa Tōhaku (1539–1610) arrived in Kyōto from the Noto Peninsula region to the north on the Sea of Japan. His training was thoroughly eclectic, with experience in Buddhist polychrome themes, portraiture, and ink monochrome. Through the offices of the tea master Sen Rikyū, Tōhaku gained access to important collections of Chinese painting that had greatly influenced Muromachi aesthetics. His acknowledged masterworks are in both the full-blown but delicately nuanced polychrome style and the more subtle, contemplative ink monochrome format. The latter style is exemplified by the hauntingly depicted pine trees obscured by a mist that he painted on a pair of sixfold screens.

The subject matter favoured by the military patrons was bold and aggressive, as overtly suggested in paintings of birds of prey, lions, and tigers. Slightly more subtle but equally assertive renderings of majestic rocks or trees were also popular. Some Confucian themes, reflective of the ideology that would be favoured even more forcefully under Tokugawa rule, were beginning to appear. Yet another theme endorsed by rulers and townspeople was a style of genre painting that celebrated the new prosperity and stability, both urban and agrarian. Panoramic and carefully detailed screen paintings laid out the bustling life of Kyōto emerging from the destruction of civil-war life.

An aberrational but richly interesting thematic interlude involved the presence of Iberian merchants, diplomats, and missionaries. These Westerners were part of the vast exploration, trade, and colonization effort that reached South America, Africa, and South and Southeast Asia. From the time of the foreigners' first arrival in 1543 until their expulsion in the 1630s, there was a modest amount of cultural transmission. During this time the Japanese commissioned liturgical implements from the West and acquired some training in Western painting techniques. Perhaps most memorably, it became fashionable to depict Western themes and screen panoramas of the foreigners active in various Japanese settings—walking in the streets of Kyōto or arriving at ports in galleons. Unlike paintings with Japanese or Chinese themes, which are read from right to left, a telling curiosity of these screens is that they are read from left to right, suggesting by composition that the foreigners would depart. This exposure to the West seems to have had little long-term effect on the Japanese visual arts of the time.

First introduction to Western culture

If the Kanō school and related interpreters advanced the themes and styles of the Muromachi period to accommodate the expansive sensibilities of the new ruling class and new social phenomena in general, yet another alignment of artistic talent offered a reexamination of the themes and expressive modes of the Heian court. The renaissance of courtly taste experimented with word and image, intermixing poetry, painting or design, lush decorative papers reminiscent of famous Heian secular and religious works, and countless narrative illustrations or allusive references to the *Tales of Ise* and to *The Tale of Genji.* It was during the late Momoyama and early Edo periods that a canonical body or stock of standardized referent classical illustrations began to coalesce.

The courtly themes were tackled by all schools but perhaps most effectively by the creative partnership of Hon'ami Kōetsu (1558–1637) and Tawaraya Sōtatsu (fl. 1600–30). Although, strictly speaking, they created most of their greatest works in the Edo period, Sōtatsu and Kōetsu developed their aesthetic sensibilities in Kyōto during the Momoyama period, and the inspiration for their later works can be found in the great creative freedom characteristic of that time.

Kōetsu and Sōtatsu

Kōetsu was raised in a family of sword experts, a discipline that required extensive knowledge of lacquer, metal, and leather. It implied an eye acutely attuned to delicate nuance in discerning the working of a blade. Kōetsu expanded his interests and training to include calligraphy and ceramics. He functioned as an impresario, bringing together talented craftsmen and artists to work on projects. None was more central to and intertwined with his reputation than Sōtatsu, a painter of fans. Both men, especially Kōetsu, had excellent connections with the aristocracy but came from artisan or merchant families. Working in collaboration, with Kōetsu acting as calligrapher, they created paintings and decorative backgrounds recalling the rich opaque texturing of an earlier illuminated sutra style.

While both men, in other contexts, demonstrated mastery of the ink monochrome form, their works in polychromy featured a trait that would be characteristic of their followers throughout the Edo period: their images are formed through arrangements of colour patterns rather than being defined by ink outlines and embellished with colour. Ink was used more sparingly and allusively than, for example, by the Kanō painters. The effect was softening, textured, and suggestive of textile patterning. Sōtatsu's lush screen painting, said to describe the scene at Matsushima Bay on Japan's northeast Pacific coast, is a superb statement of elemental power couched in a decorative mode. Reference to the various planes of Chinese painting—near, middle, and far distance—were largely abandoned, as exposition of the surface of a material became the foremost concern.

Sōtatsu and Kōetsu worked in collaboration with the wealthy merchant Suminokura Soan (1571–1632), beginning in 1604, to produce images and calligraphy for a series of luxury-edition printed books featuring renderings of classical and nō drama texts. This collaboration marked the earliest and one of the most beautiful efforts at a wider dissemination of the Japanese classics to an increasingly literate audience. The energies and talents that these men and their followers infused into the Japanese visual arts were thoroughly unique. It may be suggested, however, that their initial training in art forms other than painting brought new pragmatism and perspective to the painting world.

The tea ceremony (cha-no-yu).

Ceramics. The tea ceremony and the need for its attendant wares continued to develop during the Momoyama period. The ceremony itself enjoyed greater popularity, but the political instability of the late Muromachi and early Momoyama periods drove an important group of potters from Seto, near Nagoya, to the Mino region, somewhat northeast of their former site. It was in this area that many new and expanding commissions for tea ware were executed. Under the supervision of Mino kiln masters, subvarieties were produced, notably Shino ware, which used a rich feldspathic glaze whose random surface bursts and crackles appealed greatly to tea connoisseurs.

Raku ware

Works commissioned by the tea master Furuta Oribe (1544–1615) featured aberrant or irregular shapes, adding to the random effects of firing. In the Kyōto area raku ware was the characteristic type. This was typically a hand-shaped, low-fired, lead-glazed bowl form that had been immersed in cold water or straw immediately after being removed from the hot kiln in order to produce random, unique effects on the surface. In Kyushu, probably under the direction of Korean potters, a high-fired ceramic known as Karatsu ware was introduced in the early 1590s. The plain, unsophisticated shapes and designs of Karatsu ware made it especially popular for use in the tea ceremony. Tea wares featuring controlled peculiarities and manufactured rather than serendipitous defects were also introduced during the Momoyama period.

The Tokugawa, or Edo, period. At the death of the Momoyama leader Toyotomi Hideyoshi in 1598, his five-year-old son, Hideyori, inherited nominal rule, but true power was held by Hideyoshi's counselors, among whom Tokugawa Ieyasu (1543–1616) was the most prominent. Ieyasu assumed the title of shogun in 1603, and the de facto seat of government was moved from Kyōto to his headquarters in Edo (now Tokyo). Ieyasu completed his rise to power when he defeated the remaining Toyotomi forces in 1615. These events marked the beginning of more than 250 years of national unity, a period known as either Tokugawa, after the ruling clan, or Edo, after the new political centre.

The government system implemented by the Tokugawa rulers allowed for comparative discretionary rule within the several hundred domains, but the daimyo were required to pay periodic visits to Edo and to maintain a residence there in which family members or important colleagues remained, a gentle form of hostage holding and a major factor in the city's rapid growth.

In order to legitimize their rule and to maintain stability, the shoguns espoused a Neo-Confucian ideology that reinforced the social hierarchy placing warrior, peasant, artisan, and merchant in descending order. The early economy was based on agriculture, with rice as the measured unit of wealth. The warrior, the highest-ranking member of society, was salaried on rice and soon found his net worth fluctuating as wildly as the annual harvest yields. The merchant, on the other hand, who ranked lowest because he was understood to live off the labour of others, prospered in this time of peace and dramatic urban growth, a phenomenon that gave the lie to his theoretical value in the social order. Thus, from the inception of Tokugawa rule there was an implicit tension between the realities of a strong emerging urban culture, an inefficient agrarian economy, and a promulgated ideal of social order.

New cultural forms

The economic power of the merchant class and the expansion of the urban centres widened the audience for the arts from the traditional base of the nobility and the political elite. New cultural forms were generated, including the Kabuki theatre and the licensed brothel quarters. In a generally restrictive and controlled society, these entertainments served as a social safety valve offered by the shogunate to the merchant class (although participation in this world was egalitarian). Their popularity opened a whole new thematic source to the visual arts as the formats of woodblock print and painting were employed to depict the many facets of the pleasure quarters.

The shogunate's adaptation of Chinese concepts extended beyond Neo-Confucianism. China was again officially embraced as a source for models not only of good government but also of intellectual and aesthetic pursuits. The Chinese amateur scholar-painter (Chinese: *wen-jen,* Japanese: *bunjin*) was esteemed for his learning and culture and gentle mastery of the brush in calligraphy and painting. The Japanese interpretation of this model spawned important lineages of painting and patronage.

A final Zen Buddhist migration from China in the early and mid-17th century introduced the Ōbaku Zen sect to Japan. While not on the scale of Zen influence of previous centuries, Ōbaku monks provided the Japanese with a significant window on contemporaneous Chinese culture, particularly literature, calligraphy, and painting.

Most direct contact with foreigners was limited, however, especially after a policy of national seclusion was instituted in 1639. The Dutch trading post of Deshima in Nagasaki Harbour was Japan's primary window on the outside world, providing a steady stream of Western visual images, most often in print form and frequently once removed from Europe through a Chinese interpretation. Western themes, techniques, and certain optical technology suggested new ways of seeing to Japanese artists.

In the 19th century relations with the outside world ceased to be a controlled exercise in curiosity. Although Japan's limited natural resources offered no major temptation to colonizers, Western nations increased pressure on Japan to open its ports. The transition in sea travel from sail to steam put new demands on Western trading and naval fleets. Japan's strategic location, with its potential as a port for refueling and trade, was ever more evident. During the 1850s, treaties agreed to by a weakened shogunate raised the ire of many. In the south and west the domains of Chōshū and Satsuma, which held long-festering resentment of the Tokugawa reign, led rebellions during the 1860s. They overpowered the shogunal forces and "restored" the emperor in 1868, ending Tokugawa rule.

Nationalism

The feelings of nationalism that contributed to the imperial restoration had begun to develop in the 18th century, when a school of nativist ideology and learning arose. Partly in response to the shogunate's emulation of Chinese culture, this mode of thinking posited the uniqueness and inherent superiority of Japanese culture. In the visual arts this "national learning" (*kokugaku*) was expressed by an increase in an existing interest in courtly and classical themes.

Painting. The Kanō school of painters expanded and functioned as a kind of "official" Japanese painting academy. Many painters who would later begin their own stylistic lineages or function as independent and eclectic artists received their initial training in some Kanō atelier. Kanō Sanraku (1559–1635), whose bold patterning came closest among the early Kanō painters to touching the tastes stimulated by Tawaraya Sōtatsu and Hon'ami Kōetsu with their courtly revival style, provided a link to the generative energies that launched the school to its initial position of prominence. Kanō Tanyū (1602–74) solidified the dominant position of the Kanō school and significantly directed the thematic interests of the atelier. In a sense, the Kanō artists became the official visual propagandists of the Tokugawa government. Many of their works stressed Confucian themes of filial piety, justice, and correctly ordered society. Tanyū was not only the leading painter of the school but was also extremely influential as a connoisseur and theorist. Tanyū's notebooks containing his comments and sketches of observed paintings are a major historical source. His graceful ink and light colour rendering of Jizō Bosatsu reveals brush mastery and a thoroughly familiar, playful consideration of a Buddhist image. The youthful features of the deity are conveyed as at once fleshy and ethereal. The image is decidedly different from the gentle but stately renditions of the Kamakura period.

Two painting lineages explored the revival of interest in courtly taste: one was a consolidation of a group descending from Sōtatsu, and the other, the Tosa school, claimed descent from the imperial painting studios of the Heian times. The interpretations offered by the collaboration of Kōetsu and Sōtatsu in the late Momoyama period developed into a distinctive style called *rinpa,* an acronym linking the second syllable of the name of Ōgata Kōrin (1658–1716), the leading proponent of the style in

the Edo period, and *ha* (*pa*), meaning school or group. Sōtatsu himself was active into the 1640s, and his pupils carried on his distinctive rendering of patterned images of classical themes. Like Sōtatsu, Kōrin emerged from the Kyōto trades as the scion of a family of textile designers. His paintings are notable for an intensification of the flat design quality and abstract colour patterns explored by Sōtatsu and for a use of lavish materials. His homage to the Yatsu-hashi episode from the *Tales of Ise* is seen in a pair of screens featuring an iris marsh traversed by eight footbridges that is described in the story. Kōrin attempted this subject, with and without reference to the bridges, on several occasions and in other media, including lacquerwork. Classical literature had imbued popular culture to the extent that this single visual reference would be easily recognized by viewers of the period, permitting Kōrin to evoke a familiar mood or emotion without having to depict a specific plot incident. Other notable exponents of the *rinpa* style in the later years of the Edo period were Sakai Hōitsu (1761–1829) and Suzuki Kiitsu (1796–1858).

The Tosa school, a hereditary school of court painters, experienced a period of revival thanks to the exceptional talents and political acuity of Tosa Mitsuoki (1617–91). Mitsuoki's patronage connections to the imperial household, still residing in Kyōto, provided him with an appreciative aristocratic audience for his refined narrative evocations of Heian themes and styles. A pair of screens depicting spring-flowering cherry and autumn maple strike a melancholy chord. Attached to branches of the trees are decorated slips of paper bearing classical poems inscribed by the unseen participants in traditional court outings to celebrate the seasons. The allusion to past literary glory and to a poetry party recently dispersed suggests the mood of the court now resigned to ceremonial roles under the Tokugawa dictatorship. The Tosa atelier was active throughout the Edo period. An offshoot of the school, the Sumiyoshi painters Jokei (1599–1670) and his son Gukei (1631–1705), produced distinctive and sprightly renderings of classical subjects. In the first half of the 19th century, a group of painters, including Reizei Tamechika (1823–64), explored ancient painting sources and offered a revival of Yamato-e style.

In addition to the Kanō, *rinpa,* and Tosa styles of painting, which all originated in earlier periods, several new types of painting developed during the Edo period. These can be loosely classified into two categories: the individualist, or eccentric, style and the *bunjin-ga,* or literati painting. The individualist painters were influenced by nontraditional sources such as Western painting and scientific studies of nature, and they frequently employed unexpected themes or techniques to create unique works reflecting their often unconventional personalities.

Individualist painters

A lineage that formed under the genius of Maruyama Ōkyo (1733–95) might be summarily described as lyrical realism. Yet his penchant for nature studies, whether of flora and fauna or human anatomy, and his subtle incorporation of perspective and shading techniques learned from Western examples perhaps better qualify him to be noted as the first of the great eclectic painters. In addition to nurturing a talented group of students who continued his identifiable style into several succeeding generations, Ōkyo's studio also raised the incorrigible Nagasawa Rosetsu (1754–99), an individualist noted for instilling a haunting preternatural quality to his works, whether landscape, human, or animal studies. Yet another of Ōkyo's associates was Matsumura Goshun (1752–1811). Originally a follower of the literati painter and poet Yosa Buson (1716–83), Goshun, confounded by his master's death and other personal setbacks, joined with Ōkyo. Goshun's quick and witty brushwork adjusted to the softer, more polished Ōkyo style but retained an overall individuality. He and

his students are known as the Shijō school, for the street on which Goshun's studio was located, or, in recognition of Ōkyo's influence, as the Maruyama-Shijō school. Other notable individualists of the 18th century included Soga Shōhaku (1730–81), an essentially itinerant painter who was an eccentric interpreter of Chinese themes in figure and landscape conveyed in a frequently dark and foreboding mood. Itō Jakuchū (1716–1800), son of a prosperous Kyōto vegetable merchant, was an independent master of both ink and polychrome forms. His paintings in either mode often convey the rich, densely patterned texture of produce arrayed in a market.

Literati painting

The other new style of painting, *bunjin-ga,* is also called *nan-ga* ("southern painting") because it developed from the so-called Chinese Southern school of painting, which promoted the ideal of the learned scholar-gentleman who had no pecuniary or political interests and was unintimidated by the overly polished and spiritless examples of professional painting.

While the amateur ideal was pursued by many Japanese *bunjin,* the most remarkable of the ink monochrome or ink and light colour works were created by artists who, although generally attempting to conform to a *bunjin* lifestyle, were actually professionals in that they supported themselves by producing and selling their painting, poetry, and calligraphy. Especially notable artists from this tradition include the 18th-century masters Ike Taiga (1723–76) and Buson. Some of Taiga's most compelling works treat landscape themes and the melding of certain aspects of Western realism with the personal expressiveness characteristic of the Chinese *bunjin* ideal. Buson is remembered as both a distinguished poet and a painter. Frequently combining haiku and tersely brushed images, Buson offered the viewer jarring, highly allusive, and complementary readings of a complex emotional matrix. Uragami Gyokudō (1745–1820) achieved movements of near abstraction with shimmering, kinetic, personalized readings of nature. Tani Bunchō (1763–1840) produced paintings of great power in the Chinese mode but in a somewhat more polished and representational style. He was a marked individualist and served the shogun by applying his talents to topographical drawings used for national defense purposes. Bunchō's student Watanabe Kazan (1793–1841) was an official representing his daimyo in Edo. Through his interest in intellectual and artistic reform, he perhaps came the closest to exemplifying classic literati ideals. His accomplishments in portraiture are especially significant and reveal his keen study of Western techniques.

Woodblock prints. A movement that paralleled and occasionally intersected with the aforementioned developments in painting was that of the production of ukiyo-e, or "pictures of the floating world," which depicted the buoyant, fleeting pleasures of the common people. This specialized area of visual representation was born in the late 16th and early 17th centuries as part of a widespread interest in representing aspects of burgeoning urban life. Depictions of the brothel quarters and Kabuki theatre dominated the subject matter of ukiyo-e until the early 19th century, when landscape and bird-and-flower subjects became popular. These subjects were represented in both painting and woodblock print form.

Ukiyo-e

Woodblock printing had been a comparatively inexpensive method of reproducing image and text monopolized by the Buddhist establishment for purposes of proselytization since the 8th century. For more than 800 years no other single societal trend or movement had demonstrated a need for this relatively simple technology. Thus, in the first half of the 17th century, painters were the principal interpreters of the demimonde. The print format was used primarily for production of erotica and inexpensive illustrated novellas, reflecting the generally low regard in which print art was held. This perhaps resulted from the idea that the artist, when creating a painting, was essentially the producer and master of his own work. However, when engaged in woodblock print production, the artist was more accurately classified as the designer, who had been commissioned and was often directly supervised by the publisher, usually the impresario of a studio or other commercial enterprise.

Print production process

The simplest prints were made from ink monochrome drawings, on which the artist sometimes noted suggestions for colour. The design was transferred by a skilled carver to a cherry or boxwood block and carved in relief. A printer made impressions on paper from the inked block, and the individual prints could then be hand-coloured if desired. Printing in multiple colours required more blocks and a precise printing method so that registration would match exactly from block to block. Additional flourishes such as the use of mica, precious metals, and embossing further complicated the task. Thus, while the themes and images of the floating world varied little whether in painting or print, the production method for prints involved many more anonymous and critical talents than those of the artist-designer whose name was usually printed on the single sheet, and the mass-produced prints were considered relatively disposable despite the high level of artistry that was frequently achieved. Nevertheless, with the exponential increase in literacy in the early Edo period and with the vast new patronage for images of the floating world—a clientele and subject matter not previously serviced by any of the traditional ateliers—mass production was necessary, and new schools and new techniques responded to the market.

In the last quarter of the 17th century, bold ink monochrome prints with limited hand-colouring began to appear. "The Insistent Lover" by Sugimura Jihei (fl. *c.* 1681–1703) provides an excellent example of the lush and complex mood achievable with the medium. Within a seemingly uncomplicated composition Jihei represents a tipsy brothel guest lunging for a courtesan while an attendant averts her eyes. This scene, likely played out hundreds of times each evening in the urban licensed quarters, skillfully suggests the multileveled social games, including feigned shock and artful humouring of the insistent guest, that prevailed in the floating world. This print, too, with an almost naive representational quality, is an example of the generally straightforward, exuberant mood of the times in regard to the necessary indulgences.

From the late 17th until the mid-18th century, except for some stylistic changes and the addition of a few printed, rather than hand-applied, colours, print production remained basically unchanged. The technical capacity to produce full-colour, or polychrome, prints (*nishiki-e,* "brocade pictures") was known but so labour-intensive as to be uneconomical until the 1760s, when Suzuki Harunobu (1725?–70), whose patrons were within the shogun's circle, was commissioned to produce a so-called calendar print. Calendar manufacture was a government monopoly, but privately produced works were common. Seeking to avert any censorship, the private calendars were disguised within innocent-looking pictures. Harunobu's young woman rescuing a garment from the line as a shower bursts is an example of the technique. The ideograms for the year 1765 are part of the hanging kimono's pattern. More importantly, the work is a full-colour print. Even though it was commissioned for limited distribution, it excited general audiences to the possibilities of expanding the repertoire and appearance of woodblock prints. Harunobu's productions, through the end of the decade, elegantly suggested the new possibilities. His work so raised the level of consumer expectation that publishers began to enter full-colour production on the assumption that consumption levels would outweigh production costs. Not all prints were produced with the subtlety and care of Harunobu's, but the turn in taste toward full-colour prints, of whatever quality, was irreversible.

Full-colour prints

The last quarter of the 18th century was the heyday of the classic ukiyo-e themes: the fashionable beauty and the actor. Katsukawa Shunshō (1726–92) and his pupils dominated the actor print genre. His innovative images clearly portrayed actors not as interchangeable bodies with masks but as distinctive personalities whose postures and colourfully made-up faces were easily recognizable to the viewer. Masters at portraying feminine beauty included Torii Kiyonaga (1752–1815) and Kitagawa Utamaro (1753–1806). Both idealized the female form, observing it in virtually all its poses, casual and formal. Utamaro's bust portraits, while hardly meeting a Western definition of portraiture,

were remarkable in the emotional moods they conveyed. A mysterious artist active under the name of Tōshūsai Sharaku produced stunning actor images from 1794 to 1795, but little else is known of him.

At the close of the 18th century, a palpable tightening of government censorship control and perhaps a shift in public interest from the intense introspection provided by artists of the demimonde forced publishers to search for other subject matter. Landscape became a theme of increasing interest. In Edo the artist Katsushika Hokusai (1760–1849), who as a young man trained with Katsukawa Shunshō, broke with the atelier system and experimented successfully with new subjects and styles. In the 1820s and '30s, when he was already a man of some age, Hokusai created the hugely popular print series *Thirty-six Views of Mt. Fuji.* Andō Hiroshige (1797–1858) followed with another landscape-travelogue series, *Fifty-three Stations of the Tōkaidō,* which offered scenes of the towns and way stations on the central highway connecting Edo and Kyōto. Both these and other artists capitalized on public interest in scenes of distant places. These landscape prints in some way assuaged the restrictive travel codes enforced by the shogunate and allowed viewers imaginative journeys.

Hokusai and Hiroshige

Hokusai was also an important painter. His energetic rendering of the Thunder God is a fine example of the quirky and amusing quality of his figural painting. A characteristic swiftly modulating brush defines the figure, and light cast from an unseen source, perhaps lightning, allows for a play of light and shadow over the figure to model a sense of body volume.

Hiroshige painted as well, but his legacy is a vast number of prints celebrating scenes of a Japan soon to vanish. His "View from Komagata Temple near Azuma Bridge" is part of a series of 100 views of Edo. It demonstrates Hiroshige's finely honed abilities to effect atmosphere. The appearance of the cuckoo screeching in the sky alludes to classical poetry associated with late spring and early summer, as well as to unrequited love, while the tiny figures and the red flag of the cosmetics vendor suggest the transitory nature of life and beauty.

The depiction of famous views allowed for their idealization and also for important experiments with composition. Fragmentary foreground elements were used effectively to frame a distant view, a point of view adopted by some European painters after their study of 19th-century Japanese prints. Ironically, in their return to landscape and flora and fauna subjects, Japanese print arts revived the metaphoric vehicles of personal expression so familiar to the classic Japanese and Chinese painting traditions.

Although the time-tested themes of erotica, brothel, and theatre continued to be represented in 19th-century prints, an emerging taste for gothic and grotesque subjects found ample audiences as well. Historical themes were also popular, especially those that could be interpreted as critiques of contemporary politics. Ukiyo-e prints seemed to have been transformed from a celebration of pleasure to a means of widely distributing observations on social and political events. As the century closed, the print form, while active, was subsumed by the development of the newspaper illustration. This new form served many of the same purposes as prints and thus dramatically reduced the print audience, but it did not satisfy the needs of connoisseurs.

Ceramics. Ceramic and decorative arts flourished in the Edo period. While it was possible in almost all areas of the visual arts to accommodate the emergence of Japanese taste from the subdued or monochrome tastes of the Muromachi period to the burst of colour and pattern that was favoured in the Momoyama period, ceramics lagged behind. As the Edo period dawned, ceramic art also was able to participate in this development. Technological and supply limitations had previously hampered the ability of Japanese potters to produce a high-fired polychrome product. That problem was rectified in the early 17th century when the chambered climbing kiln was imported from Korea. This type of kiln was able to sustain controlled, high temperatures. Also, Korean potters working in western Japan discovered clay with a kaolin content high enough to allow vessels to be fired to the hard, fine surface classified as porcelain. In particular, white-glazed porcelain provided an excellent surface for the application of pigments to produce polychrome design patterns. Initial interest was in the imitation of Chinese blue-and-white ware, but the palette was quickly expanded.

Porcelain

The potter Sakaida Kakiemon (1596–1666), active in Arita in western Japan, was a pioneer in expanding the colour range and design patterns on the newly achieved creamy white surfaces. His works were especially admired in Europe. Also produced in the Arita region, by potters working for the Nabeshima clan, was a high-fired ware most frequently seen as footed shallow plates or dishes. The designs applied to the ware were typically bold and employed combinations of Yamato-e style painting and textile patterns. Kutani ware was produced in similar shapes, although denser designs and darker colours were used in the decoration. Kutani ware was primarily commissioned by the Maeda domain and, like Nabeshima ware, was not for public consumption or export.

Kyōto ceramics, already noted for the low-fired raku ware, responded to the fashion for porcelain with a break from the older traditions. Nonomura Ninsei (fl. 17th century) is the first identifiable Kyōto potter to use the high-fired, smooth-surfaced ware as a means to offer brilliantly coloured, painterly designs. Ninsei was far less interested than his predecessors in the inherent character of a vessel's randomly produced surface. His ceramic ware ranged beyond traditional vessels and included incense burners, candle holders, and other Buddhist liturgical implements. Kyōto artists who continued variations of the Ninsei legacy—referred to, after the place of production, as *kyōyaki*—included Ōgata Kōrin's brother Kenzan (1663–1743) and Aoki Mokubei (1767–1833). Kenzan's designs favoured uncomplicated and bold variations of *rinpa* painting style, while Mokubei's work reflected interest in Chinese sources.

Lacquerware. Throughout the Edo period, innovations in the production and design of lacquerware met the demands of a widening and appreciative audience. Extremely time-consuming to produce, the finished lacquer product is strong and resilient if properly handled. Ensembles for the study (such as writing tables and boxes to hold ink stones and brushes), furniture, and dining ware were among the most frequent uses. Paralleling in many ways the trends in ceramics, Edo-period lacquerware shifted from the sedate and simple styles of the Muromachi period as a taste for remarkably striking and complex objects developed. A delight in trompe-l'oeil was increasingly evident.

Lacquer was typically used for constructing *inrō,* the small, often multitiered and compartmentalized case that hung from a gentleman's kimono sash and held small belongings. It is perhaps in this format, especially from the late 18th century, that lacquer artists were most inspired by novelty and new fashions, such as the taste for verisimilitude. A lacquer *inrō* could be made to look as if it were made, for example, of aged and rotting wood or animal skin. Technically remarkable and frequently ingenious in construction and design, these and other objects were the aesthetic opposites of such early lacquer examples as Negoro ware. The later efforts seemed intent on disguising rather than revealing component materials.

Lacquer *inrō*

Architecture and garden design. Architectural developments reflected the major tendencies found in other aspects of the visual arts. There were the quite differing perspectives provided by the aristocratic revival and the bombastic display favoured by the newly powerful. The mausoleum of Tokugawa Ieyasu, begun in 1636 and located in the mountainous area of Nikkō, north of Edo, features an abundance of polychrome decorative carving and exaggerated curving lines and is perhaps the quintessence of the floridly decorated, ostentatious form. But much residential architecture also began to feature elaborate decorative carvings on interior and exterior panels and joints.

The Katsura Imperial Villa, built between 1620 and 1624 on the southwestern edge of Kyōto, is the most outstanding example of a cohesive attempt to integrate a mannered interpretation of Heian styles with the architectural innovations spurred by the development of the tea ceremony. Carefully planned meandering paths lead to and from

the central structures through gardens dotted with small pavilion structures and tea huts offering orchestrated and allusive views. Perhaps a more moderate and quite beautiful example suggesting more subdued tastes within the shogunal and daimyo ranks is Kenroku Garden and its surrounding structures, located at Kanazawa, capital of the Maeda family domain on the Sea of Japan northeast of Kyōto. In general, the Edo garden, which underwent various refinements throughout the period, is bold and beautiful but more obviously crafted than the tea gardens of the Muromachi period. Nature's flaws have been disguised and the hand of the landscaper shows clearly.

Sculpture. Sculpture did not enjoy a great infusion of creativity during the Edo period. More obviously mannered and stylized interpretations of Buddhist deities and worthies were regularly produced. There were, of course, some sculptors of exceptional talent. Shōun Genkei (1648–1710) is renowned for his production (1688–95) of a set of 500 arhats (disciples of the Buddha) at Gohyaku Rakan Temple in Edo. His inspiration came from exposure to Chinese sculpture imported by Ōbaku Zen monks at Manpuku Temple to the south of Kyōto. Another expressive and thoroughly individualistic sculptor of the Edo period was the itinerant monk Enkū (1628?–95). He produced charming and rough-featured sculptures revealing bold chisel marks. His goals were to inspire faith and to proselytize. His works are totally without artifice, and the energy and power of his efforts are clearly conveyed.

Modern period. Japan's modern period is, for the purposes of this article, defined as beginning with the Meiji Restoration in 1868 and continuing through to the present. In the Japanese system of dating, this period encompasses the Meiji period (1868–1912), the Taishō period (1912–26), the Shōwa period (1926–89), and the Heisei period (1989–).

International relations

Modernity for Japan has been a process of seeking definition in its cultural and political relationships with other nations, both Asian and Western. Japan's official intentions toward the West during the Meiji period can be described as a calculated attempt to achieve Western industrial standards and to absorb Western culture at every possible level. Also during this time Japan was directly involved in two international conflicts: a war with China (1894–95) and a war with Russia (1904–05). Victorious in both these conflicts, Japan proved its ability to gear its newly established industrial base to the achievement of foreign expansionist goals. In 1910 Japan officially annexed Korea, a process it had begun in 1905 when it assumed a protectorate status over the peninsular nation. Japan's pretext was to establish a strong buffer zone against possible Western incursion, but Korea was essentially colonized as a source of labour and natural resources.

The Taishō period was characterized by a comparatively liberal mood both politically and in the arts. In retrospect it has been sometimes viewed as a romantic, euphoric period of cultural creativity following the more conservative Meiji era and preceding the militaristic mood of the 1930s. During this same period, as the Western powers with colonial and mercantile interests in Asia were forced to focus their attention on Europe during World War I (1914–18), Japan moved in to fill the vacuum, especially in China. The 1930s were characterized by a rise in militarism and further expansion on the Asian continent. This process culminated in World War II and in Japan's defeat by Western powers in 1945. The postwar period began with the Allied—almost exclusively American—occupation of Japan and was characterized by rebuilding, rapid growth and development, and increasing internationalism.

The development of the visual arts since 1868 has been considerably influenced by changing political climates and goals. Assuming an official posture of encyclopaedic investigation and selective assimilation of Western culture and technology in the late 19th century, the Japanese cultural mainstream was systematically infused with the classical forms of Western painting, sculpture, and architecture. In the first several decades of the Meiji period, there was an upheaval in patronage and in the status of the traditional Japanese artist. The Meiji government pursued a policy of officially separating whatever elements of Buddhism and Shintō had been joined over the centuries in Buddhism's attempt at a syncretic relationship with the indigenous religion. Buddhism was stripped of many tax privileges. There was, as well, a sometimes violent and destructive reaction to Buddhism owing to strong nativist sentiments. The cumulative effect of this official dismantling and unofficial persecution was to release a remarkable amount of Buddhist art onto the market. Temples were forced to divest in order to support themselves, and the patronage supplied to artists who created Buddhist iconography was seriously curtailed. Japanese artists also suffered because of the general trend to idealize all aspects of Western culture. Vast amounts of Japanese art, woodblock prints being the foremost example, went to Western collections.

Influence of Ernest Fenollosa

This trend began to be reversed in the 1880s owing in part, ironically, to the efforts of Ernest Fenollosa (1853–1908), a recent Harvard graduate who arrived in Japan in 1878 as a philosophy instructor at the Tokyo Imperial University (now University of Tokyo). His avocational interest in Japanese and Chinese art became his passion. The Japanese reshuffling of cultural priorities placed him in a particularly advantageous position to acquire Japanese art—especially Buddhist art—of exceptional quality for Western collections. Working with a former student, Okakura Kakuzō (1863–1913; also known as Tenshin), Fenollosa also moved forcefully to influence the Japanese to reclaim their cultural heritage and to adapt creatively to changing tastes.

The Japanese government sponsored the participation of Japanese artists and craftsmen in various late 19th- and early 20th-century international expositions held in Europe and America. These were of some help in advancing Western knowledge of Japanese culture. Collecting of the type endorsed by Fenollosa, as well as more popular collecting inspired by the flood of Japanese arts and crafts to Western markets, caused Westerners to take notice of a theretofore unknown visual arts tradition. This Western assessment of Japanese art was done in piecemeal fashion. Some obvious and immediate results included the influence of Japanese art on European and American painters and printmakers as well as the wider trend to Japanism. This initiation of communication between disparate visual worlds began the lengthy process of asserting the Japanese fine arts tradition within the context of world culture.

The early 20th century was not only a time of continued assimilation of Western art forms and philosophies but also a period in which traditional Japanese forms sought and achieved a new interpretive voice. With the rise of militarism, the visual arts were largely conscripted for straightforward propagandistic purposes or allowed only in thematically banal forms. Japan's defeat in World War II produced in many Japanese intellectuals and artists a distrust of the authority of the indigenous tradition, leading them to search for meaning in artistic movements and traditions abroad. Meanwhile, the postwar Allied occupation forces (1945–52) urged structural changes to ensure that Japan's cultural properties were properly honoured, protected, and made more widely available to general audiences. Censorship of contemporary materials, particularly for political content, continued to be imposed. In general, however, the occupation opened the way for international cross-cultural experimentation and the development of an "international style" that persists to the present.

Western-style painting. As early as 1855, preceding the Meiji Restoration, the Japanese established a bureau (later named Bansho Shirabesho, "Institute for the Study of Western Documents") to study Western painting as part of an effort to master Western technology. Technical drawing was emphasized in the curriculum. Takahashi Yuichi (1828–94), a graduate of that bureau, was the first Japanese artist of the period to express an artistic rather than strictly technical interest in oil painting. Through self-training and in consultation with the British illustrator Charles Wirgman (1835–91), then in Japan, his level of mastery increased. His "Still Life of Salmon" (1877), one of seven known attempts by Takahashi at the subject, elevates this ordinary subject to a splendid study of form and colour.

A school of fine arts was established in 1876, and a team

of Italian artists was hired to teach Western techniques. Most influential among them was Antonio Fontanesi (1818–81). Active as an instructor in Japan for only a year, Fontanesi, a painter of the Barbizon school, established an intensely loyal following among his Japanese students. His influence is seen in the works of Asai Chū (1856–1907), who later studied in Europe. Asai's contemporary Kuroda Seiki (1866–1924) studied in France under Raphael Collin and was among the most prominent exponents of a style that was strongly influenced by Impressionism in its informality and its use of lighter, brighter colours.

In general it can be observed that in the Meiji period there was an initial calculated strategy to study Western representational methods for the larger purpose of bringing Japan to a perceived level of modernity. However, a small but influential group of painters became involved in a cross-cultural exchange that could not be controlled by government planning. Oil paintings that vary in skill of execution from awkward to highly competent were produced during this time. Unlike the comparatively sympathetic modes of painting that Japan assimilated from China, Western painting posed conceptual as well as technical challenges. Not only did unfamiliar materials such as oil and canvas have to be mastered but also new theories of composition, shading, and perspective—and the underlying Western philosophy of nature and its representation that had led to their development over the centuries—had to be absorbed.

The close of the Meiji period saw greater rigidification of painting schools, affiliations, and systems of official recognition through annual exhibitions. There were government-sponsored exhibitions and associations as well as protest salon or secessionist groups indicating a lively spirit of resistance to official control.

An increasingly sophisticated understanding of European art and cultural trends marked the Taishō period. The humanistic literary journal *Shirakaba* ("White Birch") was devoted to and highly influential on these subjects, and it was instrumental in introducing Japanese artists to European Impressionism and Postimpressionism. Its publication period (1910–23) essentially spanned the Taishō era. The paintings of Kishida Ryūsei (1891–1929) exemplify the extensive assimilation of sympathetic European moods into a Japanese mode. Kishida was a devoted follower of the Dutch painter Vincent van Gogh and later of artists of the Northern Renaissance such as Albrecht Dürer and Jan van Eyck. "Reiko with a Woolen Shawl" (1921), Kishida's portrait of his six-year-old daughter, attributes a knowing maturity to the sitter, an effect achieved, in part, through a slight distortion of features to produce a gnomelike adult visage.

The conscription of efforts during the war years enforced on the visual arts choices of severe puritanism, blithe optimism, or heroism. The work of Umehara Ryūzaburō (1888–1986) is a case in point. In the early 20th century he studied with Asai Chū and in France with Pierre-Auguste Renoir. His ebullient palette and love of patterning, as seen in his famous "Tzu-chin-ch'eng Palace" (1940), convey a cheerful mood. Not revealed in the painting is its occasion: the artist is present in Peking (Beijing) as part of an occupying force in the midst of war.

In the postwar period Japanese artists enjoyed widely increased access to Western sources and the ability to travel more freely in the West. As a result, practitioners of virtually all modern artistic movements and styles—including abstract expressionism, minimal and kinetic art, op and pop art—can be found in Japan.

Japanese-style painting. Paralleling the intensive and systematic study of Western painting methods was a steady process of renewal occurring in the field of traditional painting. Fenollosa was particularly instrumental in redirecting and salvaging the careers of two important late 19th-century painters, Kanō Hōgai (1828–88) and Hashimoto Gahō (1835–1908). Fenollosa had particular notions about the ways these traditional Kanō-school painters could adapt their techniques in order to create a more exciting and, perhaps to Western eyes, a more marketable product. He encouraged the use of chiaroscuro, brilliant palettes, Western spatial perspective, and dramatic atmospherics, and these techniques were indeed effective in creating new interest in the previously moribund forms of traditional Kanō painting.

A generation of painters inspired by the success of Hōgai and Gahō sought to expand the technical adaptations of these masters. Shimomura Kanzan (1873–1930), Yokoyama Taikan (1868–1958), and Hishida Shunsō (1874–1911) stand at the beginning of the *nihonga* ("Japanese painting") movement, in which traditional Japanese pigments were used but with a thematic repertoire much expanded. Format was no longer limited to scroll or screen and included occasional Western framed paintings. Shimomura's portrait of Okakura Kakuzō pays homage to Okakura's role as a mentor to the movement. This is a preparatory sketch for a completed portrait unfortunately destroyed in the Great Kantō Earthquake of 1923. Yokoyama and Hishida sought out more international, often Asian, themes. Their *nihonga* used the materials of traditional Yamato-e painting but, like the later Kanō paintings, incorporated heightened dramatic and atmospheric effects.

The *nihonga* movement

Maeda Seison (1885–1977), prominent in the next generation of *nihonga* artists, which also included Imamura Shikō (1880–1916), Yasuda Yukihiko (1884–1978), Kobayashi Kokei (1883–1957), and Hayami Gyoshū (1894–1935), employed an eclectic assortment of earlier Japanese painting techniques. At Okakura's suggestion he studied *rinpa.* His use of *tarashikomi,* a classic *rinpa* technique that achieves shading through pooling successive layers of partially dried pigment, clearly points out his wide-ranging adaptation of traditional techniques. Seison and others of his period were especially fond of historical subjects.

A somewhat distinct tradition of *nihonga* developed in Kyōto, finding natural precedents in the lyrical realism of the Maruyama-Shijō school of painters. Takeuchi Seihō (1864–1942) was the most successful proponent of this lineage. Interestingly, his most distinguished student was Uemura Shōen (1875–1949), a woman who revived a style reminiscent of ukiyo-e beauty portraits but instead idealized women in domestic settings.

Nihonga continued to flourish after World War II. This essentially traditional style was energized, like other Japanese art forms, by the openness of the postwar years. Traditional themes of flora, fauna, and landscape were joined by abstractions and by modern urban and industrial scenes. The resulting works, which use traditional pigments and brushes, provide a curious Japanese version of modernism.

The literati movement seemed to proceed with the least disruption of any of the traditional lineages. Tomioka Tessai (1837–1924) stands out as perhaps the latest of the literati masters. Noted for dense, rough brushwork and occasionally jarring choices in bright pigments, his creations were animated, cheerful evocations of Sung dynasty poetry.

Woodblock prints. The world of woodblock prints was profoundly affected by the changes ushered in during the Meiji period. The print medium had long served both connoisseur and general audience. With the advent of mass-circulation newspapers, however, the latter group was coopted. Illustrators and designers produced reportorial images and cartoons for newspapers, satisfying the public demand for illustration but removing a large block of economic support from the traditional print publishers. Print artists nevertheless continued to document the remarkably varied moods of the period. For example, a type of print known as Yokohama-e, named after the Japanese port city with a large resident foreign population, offered glimpses of the customs and appearances of the recently arrived visitors. Brutal, grotesque, and dark-humoured visions by such artists as Kawanabe Gyōsai (1831–89) and Tsukioka Yoshitoshi (1839–92) suggested that assimilation with the West was a socially and psychically traumatic process. Kobayashi Kiyochika (1847–1915), a student of Charles Wirgman as well as of Gyōsai, is best known for his prints illustrating the Sino-Japanese War and for his highly successful visions of contemporary Tokyo.

In the early 20th century two general currents moved the print world. The *shin hanga* ("new print") movement

The *shin hanga* movement

sought to revive the classic ukiyo-e prints in a contemporary and highly romanticized mode. Landscapes and women were the primary subjects. Watanabe Shōsaburō (1885–1962) was the publisher most active in this movement. His contributing artists included Kawase Hasui (1883–1957), Hashiguchi Goyō (1880–1921), Yoshida Hiroshi (1876–1950), and Itō Shinsui (1898–1972). Hashiguchi was determined to have complete control over his artistic output, and his tenure as a Watanabe artist was brief. His prints numbered only 16 and were mostly studies of Taishō women in a fashion thoroughly reminiscent, in technique and in composition, of Utamaro.

The other woodblock print trend was *sōsaku hanga,* or "creative print," a movement modeled on European approaches to print production. The artist, instead of consigning his designs to the carvers and printers employed by the publisher, performed all aspects of production. This was a philosophy of total engagement with the work. The leader of this movement was Onchi Kōshirō (1891–1955). Also prominent was Yamamoto Kanae (1882–1946). A notable feature of *sōsaku hanga* works was a movement toward defining shapes using colour rather than outlines, as in traditional woodblock prints.

"On Deck," woodblock print by Yamamoto Kanae, *c.* 1917. In the Art Institute of Chicago. 15.5 × 18.5 cm.

The print medium continues to be a particularly fertile arena of development in the Japanese visual arts. The use of the woodblock print has largely been usurped by lithography and other techniques, although there are periodic resurgences of interest in woodblock. Themes vary widely from traditional representational to abstract. The relatively inexpensive and easily portable format has made the modern Japanese print, and thus Japanese visions of modernity, widely available to international collectors.

Sculpture. Sculpture in the modern period was most productive in the bronze medium. The Italian Vincenzo Ragusa, along with other foreign technical experts recruited in the late 1870s, was a major influence in instructing young Japanese artists in bronze casting, although he privately despaired of their abilities at three-dimensional conceptualization. Japanese sculptors applied the new format to nonreligious subjects, including portraits and studies of anonymous subjects in a celebration of Japanese physical types. Takamura Kōtarō (1883–1956) was particularly influenced by Auguste Rodin, as was Ogiwara Morie (1879–1910), who produced notably fine heroic figures.

In the postwar period, Japanese sculptors and their works became more visible at international art fairs and competitions. As in other media, traditional formats fell from favour. Abstract forms have dominated the contemporary sculptural field, which has also been marked by experimentation with diverse materials. Installation art has joined the larger sculptural repertoire, and outdoor sitings—both in open natural spaces and in urban environments—have attracted much interest. Massive creations in bamboo and other works that interact with the environment are especially popular.

Ceramics. In addition to the continuation of various traditional lineages, the most significant development in ceramics of the modern period was the return to folkcraft tastes. Yanagi Sōetsu (1889–1961) espoused anonymity, functionality, and simplicity as a corrective to the industrialism and self-aggrandizement characteristic of the age. In league with potters such as the British artist Bernard Leach (1887–1979), Hamada Shōji (1894–1978), and Kawai Kanjirō (1890–1966), Yanagi engendered a robust, charming type of ceramic which recalled the wares that appealed to tea masters of the Muromachi and Momoyama periods. Kitaōji Rosanjin (1883–1959) was the major exponent of highly decorated work in the Kutani and later *kyōyaki* traditions. His role was largely as designer and production manager. Long associated with a famous restaurant, he was most conscious of the choreography of a total sensory experience in which his wares were an essential element.

Contemporary Japanese ceramics follows both traditional and abstract lines. Developments have been marked by wide experimentation in form and a general movement from traditional, functional pieces to "art" or sculptural works. The line between sculptor and ceramicist has become increasingly blurred.

Architecture. Japanese architecture created from the last quarter of the 19th century is remarkable in its rapid assimilation of Western architectural forms and the structural technology necessary to achieve results quite foreign to traditional Japanese sensibilities. Large-scale official and public buildings were no longer constructed of wood but of reinforced brick, sometimes faced with stone, in European styles. Steel-reinforced concrete was introduced in the Taishō period, allowing for larger interior spaces.

English and German architectural influences

The English architect and designer Josiah Conder (1852–1920) arrived in Japan in 1877. His eclectic tastes included adaptations of a number of European styles, and the work of his Japanese students was significant through the second decade of the 20th century. The Bank of Japan (1890–96) and Tokyo Station (1914), designed by Tatsuno Kingo (1854–1919), and the Hyōkeikan (1901–09), now an archaeological museum within the complex of buildings at the Tokyo National Museum, and the Akasaka Detached Palace (1909), both by Katayama Tōkuma (1853–1917), are but a few of the best-known examples of Japanese attempts at stately monumentality in a Western mode.

The German architects Hermann Ende and Wilhelm Böckmann were active in Japan from the late 1880s. Their expertise in the construction of government ministry buildings was applied to the growing complex of such structures in the Kasumigaseki area of Tokyo. The now much-altered Ministry of Justice building (1895) is a major monument to their work. The Germans also trained a group of protégés, including Tsumaki Yorinaka (1859–1916). His design of the Nippon Kangyō Bank (1899; no longer extant) and Okada Shinichirō's (1883–1932) Kabuki Theatre (1924) in Tokyo are representative of attempts to combine the grand scale of Western buildings with such traditional elements of Japanese architecture as tiled hip-gabled roofs, curved Chinese gables, and curved, overhanging eaves.

The striving for monumentality reached its most awkward form in the highly nationalistic period of the 1930s. The Tokyo National Museum (1937) by Watanabe Hitoshi and the Diet Building (1936), Tokyo, designed by Watanabe Fukuzo are examples of massive, blocky scale without grandeur.

Frank Lloyd Wright's Imperial Hotel in Tokyo (1915–22; dismantled in 1967) seemed to have little lasting influence, although Wright's creations in the West revealed his indebtedness to his perceptions of the Japanese aesthetic. Similarly, the Bauhaus movement stirred interest in Japan, but Walter Gropius was even more thoroughly impressed and influenced by such Japanese classics as the Katsura Imperial Villa in Kyōto.

Postwar architecture, while widely eclectic and international in scope, has seen its most dramatic achievements in contemporary interpretations of traditional forms. The structures created for the 1964 Tokyo Olympics by Tange Kenzō (b. 1913) evoke early agricultural and Shintō architectural forms while retaining refreshing abstraction. The residential and institutional projects of Andō Tadao (b. 1941) are marked by stark, natural materials and a careful integration of building with nature. In general, Japanese architects of the 20th century have been fully conversant in Western styles and active in developing a meaningful modern style appropriate to Japanese sites. (J.T.U.)

MUSIC

A study of the music of East Asia covers historical periods of changing styles from at least 2,000 BC to the present time. After a general introduction, the development of the musical systems of China, Korea, and Japan will be reviewed separately in chronological order.

The nature of East Asian music

EAST ASIAN MUSIC VIS-À-VIS THAT OF OTHER MAJOR CULTURES

East Asia can be viewed as one of the big four among the generally urban, literate cultural areas of the world. The other three are South Asia, the Middle East, and Europe. Around each of these major regional cultures one can find many satellite musical systems known as national forms. In most cases, the fundamental musical concepts of such national forms reflect the basic ideals of the cultural core.

Intercultural influences

Using instrument type alone as a measure, it is sometimes possible to note cultural influences and mixtures of the major traditions in smaller units. For example, the physical structure and playing positions of various bowed instruments in mainland Southeast Asia can often mark clearly Chinese influence, as in Vietnam, or Muslim and Chinese forms in confluence, as in the various bowed lutes of courtly ensembles in Cambodia and Thailand.

Concepts of music. If one turns to distinctions in musical style, one of the first questions to arise is "What is music?" Two basic definitions will suffice for the present discussion. The first definition is cultural: a sonic event can be called music if the people who use it call it music, regardless of one's own reaction to it. Similarly, certain events that sound musical to foreign ears are not music culturally if they are not accepted as such by native culture carriers. A good example of such a situation is found in the Middle East, where singing is never allowed in the mosque, though one may hear performances and even buy records of "readings" from the Qur'ān. Such cultural and functional problems of definition seldom arise in East Asian music, and a more neutral definition is appropriate. A sound event may be considered and studied as music if it combines the elements of pitch, rhythm, and loudness in such a way that they communicate emotionally, aesthetically, or functionally on the levels that either transcend or are unrelated to speech communication. Those who have been moved by a love song or a lament can well appreciate some of the implications of such a view of music. When listening to "exotic" music—*i.e.*, that of a tradition outside one's own background—it is important to remember that such transcendental values are at work for the alien listener as well as for listeners familiar with the particular musical language in use.

There are many kinds of music in the world, the three most common terms being folk, popular, and art music. Folk and popular music have their special indigenous and mixed forms in Asia (as in all the world today), but it is in the literate art traditions of Asia that historical and musical distinctions can be made most clearly. In the context of this discussion, art music is defined as a tradition having, to some degree, a conscious theoretical basis and a sense of repertoire that is played against the highest standards held by informed native listeners. The performer is often a professional, and there may be a known historical depth to the traditions. Thus, there may be art music in many nonliterate cultures such as that of the Australian Aborigines and that of the tribal courts of Africa. Here, however, the major concern is with one of the large urban, literate cultures and its three national variants. Before looking at these musical systems in detail, it is useful to compare the entire culture with those of the other major "big" three, South Asia, the Middle East, and Europe.

Theoretical systems. All four major literate cultures, in their ancient forms, laid a strong emphasis on the extramusical qualities of music. For example, the study of such concepts as the power of vibrations (in ancient Indian music theory) and the relationships between music and other elements in the universe (in Assyrian records as well as in the writings of medieval European scholars) can be matched in East Asia by the joint efforts of Chinese musicologists and astrologers to bring the music of the empire in tune with the universe.

In addition, all four cultures developed mathematically and acoustically based music theories. The pitches produced by dividing the length of a string were the basis of the three non-East Asian music theories. String acoustics were known in China as well, but, as described below, East Asian writings use the overtones of end-blown bamboo tubes to illustrate their systems. It is fascinating that, whatever their origin, the Middle Eastern and South Asian theories produced highly variable tone systems while the two ends of the old continent (*i.e.*, the West and China) generated 12 tones based on a cycle of pitches 5 tones apart (such as C to G to D in the West). This cycle of fifths produced 12 pitches that were mathematically correct, but the 13th pitch did not match the 1st pitch. In the West this so-called "Pythagorean comma" became bothersome as Western music oriented toward vertical sounds called harmony in which the distance between pitches in chords needed to be the same in every key. In the 17th century Western acousticians developed a formula that allowed them to bypass the "natural" tone system by making all pitches equidistant. The same formula was discovered by a Chinese mathematician and musicologist, Chu Tsai-yü, in the late 16th century; but such "well-tempered" tuning was not accepted in Chinese music practice until very recently, when Western music styles combined with indigenous traditions. This is one reason why Asian music sometimes sounds "out of tune" to Western ears.

The scientific base of music is reshaped by each culture into a system that meets its needs and tastes. There are differences in the sound, the instrumentation, and the forms of Western and Eastern music. Many will be noted in the subsequent chronological study of East Asian music. However, if the wonder of such variants is to be fully appreciated, it must be understood that music is not in fact an international language. It consists of a whole series of equally logical but sometimes very different closed systems. The word closed is used to mean that the musical facets mesh perfectly within a given system, but they often may prove difficult or impossible to transfer to another system. In this light, a given passage of Chinese music when analyzed or judged with the logic of Beethoven is chaos, but Beethoven seems equally illogical when viewed in the context of Chinese, or for that matter Indian, music theory. Such intercultural clashes can be constructed between almost any of the larger systems. In this context, one can see that Chinese music is tonally more foreign to Middle Eastern or Indian music than to Western, though historically it had closer relations with the other two. There are, of course, many other musical concepts and styles that traveled over the Silk Road between China and other parts of Asia; but these must be held aside until the discussion of the history of Chinese music.

Internally logical, closed systems

MUSICAL TRAITS COMMON TO EAST ASIAN CULTURES

In these primary considerations a view of some general aesthetic traditions common to much of East Asian music

is also requisite. The tonal vocabulary of 12 tones generated in a cycle of fifths is the first common factor. From this tonal vocabulary various scales of five to seven notes are chosen. Specific examples are found below in each area study. As in the West, the total number of notes in an East Asian scale is often seven, but each scale tends to have what could be called a five-tone (pentatonic) core (see notations III, VIII, and IX below). The one scale in which no half steps appear (the so-called anhemitonic pentatonic) is common all over the world, although casual listeners often mistake it as being characteristically "Oriental." A study of the scales found in this article or a few moments spent listening to authentic East Asian recordings will reveal clearly that the five black notes on the piano do not represent all the sonic resources of Asian music. Indeed, there are a great variety of East Asian musics. Their three most common characteristics are linearity, transparency, and word orientation.

Linearity

Linearity means an emphasis on melodic tension and release supported by or held in further tension by rhythmic devices. This line-and-rhythm orientation and lack of interest in Western-style harmony are, in fact, major distinctions between most of the world's music and that of the West. In traditional East Asian music, as well as in most other non-Western traditions, all melodic instruments play the same basic melody. No one fills in the texture with chords. If harmonic texture is used, its function is to provide colour rather than to generate tension or release by chord progression. Heterophony (more than one version of the melody being heard at the same time) may occur to enrich the line. The sense of moving through a time continuum toward an ending, however, is basically developed through the tension produced during the wait for a pitch to resolve to a pitch of rest just one tone above or below.

Transparency refers to the preference in East Asian music for chamber-music sound ideals; no matter how large an ensemble may be, the individual instruments are meant to be heard. This differs from the orchestral sound ideal, popular in 19th-century Western music, in which the intention is to merge the sounds of the individual instruments into one musical colour. A transparent texture is a logical choice for a tradition that wishes to emphasize lines; orchestral colour helps to merge various lines into single vertical sonic events called harmony.

Word orientation refers to the fact that until the 20th century there was little abstract instrumental music, such as a sonata or a concerto, in East Asia. A piece had either a text or a title that evoked an image, such as "Moon over the River" or "Spring Sea." Perhaps this relates to a general sensitivity to nature in East Asian culture as a whole. Whatever its source, it has produced many sonorous and pleasing results.

The music of China

One always approaches any survey of Chinese music history with a certain sense of awe—for what can one say about the music of a varied, still active civilization whose archaeological resources go back to 3000 BC and whose own extensive written documents refer to endless different forms of music in connection with folk festivals and religious events as well as in the courts of hundreds of emperors and princes in dozens of different provinces, dynasties, and periods? If a survey is carried forward from 3000 BC, it becomes clear that the last little segment of material, from the Sung dynasty (AD 960–1279) to today, is equivalent to the entire major history of European music. For all the richness of detail in Chinese sources, it is only for this last segment that there is information about the actual music itself. Yet the historical, cultural, instrumental, and theoretical materials of earlier times are equally informative and fascinating. This mass of information will be organized into four large chronological units: (1) the formative period, from 3000 BC through the 4th century AD, (2) the international period, from the 4th through the 9th century, (3) the national period, from the 9th through the 19th century, and (4) the world music period of the 20th century.

FORMATIVE PERIOD

Ancient artifacts and writings. Chinese writings claim that in 2697 BC the emperor Huang-ti sent a scholar, Ling Lun, to the western mountain area to cut bamboo pipes that could emit sounds matching the call of the phoenix bird, making possible the creation of music properly pitched for harmony between his reign and the universe. Even this charming symbolic birth of music dates far too late to aid in discovering the melodies and instrumental sounds accompanying the rituals and burials that occurred before the first historically verified dynasty, the Shang (mid-16th to mid-11th century BC). The beautiful sounds of music are evanescent, and before the invention of recordings they disappeared at the end of a performance. The remains of China's most ancient music are found only in those few instruments made of sturdy material. Archaeological digs have uncovered globular clay ocarinas (*hsün*), tuned stone chimes (*ch'ing*), and bronze bells (*chung*); and the word *ku*, for drum, is found incised on Shang oracle bones.

Chou dynasty musical documents

The earliest surviving written records are from the next dynasty, the Chou (1111–255 BC). Within the famous Five Classics of that period, it is in the *Li chi* ("Record of Rites") of the 2nd century BC that one finds an extensive discussion of music. The *I Ching* ("Classic of Changes") is a diviner's handbook built around geometric patterns, cosmology, and magic numbers that indirectly may relate to music. The *Ch'un-ch'iu* ("Spring and Autumn") annals, with its records of major events, and the *Shu Ching* ("Classic of History"), with its mixture of documents and forgeries, contain many references to the use of music, particularly at court activities. There are occasional comments about the singing of peasant groups, which is an item that is rare even in the early historical materials of Europe. The *Shih Ching* ("Classic of Poetry") is of equal interest, for it consists of the texts of 305 songs that are dated from the 10th to the 7th centuries BC. Their great variety of topics (love, ritual, political satire, etc.) reflect a viable vocal musical tradition quite understandable to modern radio or record listeners. The songs also include references to less durable musical relics such as the flutes, mouth organ (*sheng*), and, apparently, two forms of the zither (the *ch'in* and the *se*).

Aesthetic principles and extramusical associations. Despite the controversial authenticity and dates of ancient Chinese written sources, a combined study of them produces tantalizing images of courtly parties, military parades, and folk festivals; but it does not provide a single note of music. Nevertheless, in keeping with the prehistoric traditions of China, the philosophies of sages, such as Confucius (K'ung-fu-tzu, 551–479 BC) and Mencius (Meng-tzu, *c.* 371–*c.* 289 BC), and the endless scientific curiosity of Chinese acousticians furnish a great deal of rather specific music theory as well as varied aesthetic principles. The straightest path to this material is found on the legendary journey, mentioned earlier, of Ling Lun in search of bamboo pipes. The charm of such a tale tends to cloud several interesting facts it contains. First, it is noteworthy that the goal of the search was to put music in tune with the universe. This extramusical need was noted earlier in the general discussion of world music history. It is upheld in theory in the "Annotations on Music" ("Yüeh-chi") section of the *Li chi* with such comments as "Music is the harmony of heaven and earth while rites are the measurement of heaven and earth. Through harmony all things are made known, through measure all things are properly classified. Music comes from heaven, rites are shaped by earthly designs." Referring back to the previously given general definition of music, it can be seen that such cosmological ideals may be not merely ancient superstitions but actually cogent insights into the cultural function of music in human societies. Confucius, as pictured in *The Analects* written long after his death, had a similar view of music, including a concern for the choice of music and modes proper for the moral well-being of a gentleman. It is an open question as to how much performance practice followed the admonitions and theories of the scholars; but centuries later one finds numerous pictures of the wise man standing before some

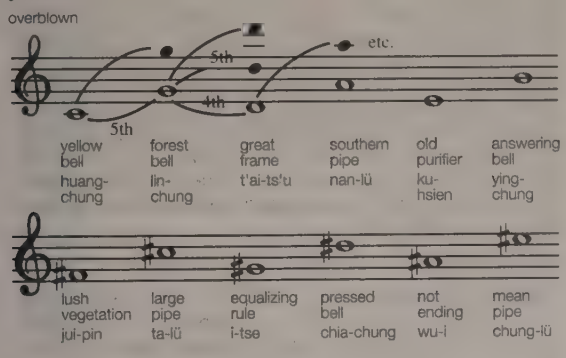
natural beauties while his servant follows closely behind him carrying his seven-stringed zither (*ch'in*) for proper use in such a proper setting.

Another point to be noted in the legend of the origin of music is the fact that Ling Lun went to the western border area of China to find the correct bamboo. It shall be noted as this article progresses how often cultures from Central and West Asia or tribal China influenced the growth and change of music in Imperial China. Finally, it is significant that, although the emperor in the myth was primarily concerned with locating pipes that would bring his reign into harmony with the universe, the goal was also the creation of precise, standard pitches.

Tonal system and its theoretical rationalization. As noted earlier, harmonic pitches produced by the division of strings were known in China. They may have been used to tune sets of bells or stone chimes, but the classical writings on music discuss a 12-tone system in relation to the blowing of bamboo pipes (*lü*). The first pipe produces a basic pitch called yellow bell (*huang-chung*). This concept is of special interest because it is the world's oldest information on a tone system concerned with very specific pitches as well as the intervals between them. The precise number of vibrations per second that created the yellow bell pitch is open to controversy (between middle C-sharp (C♯) and the F above) because the location of this pitch could be changed by the work of new astrologers and acousticians on behalf of a new emperor, in order that his kingdom might stay in tune with the universe. (The note C is used in notation I in deference to Western readers; it should not be assumed that a pitch identical to C♯ was necessarily central to ancient Chinese music). The choice of the primary pitch in China had extramusical as well as practical applications, for the length of the yellow bell pipe became the standard measure (like a metre); and the number of grains of rice that would fill it were used for a weight measure. Thus, the pipe itself was often the property not of the Imperial music department but of the office of weights and measurements.

Practical applications of Chinese music

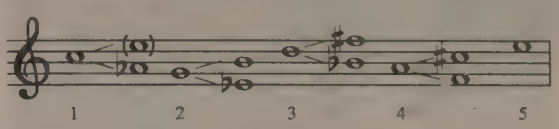
I



Mathematical relationship of pitches. The bamboo *lü* pipe is closed at the bottom by a node in the bamboo, with the result that another pitch a fifth and one octave higher could be produced on it by blowing more strongly (overblowing) as shown in notation I. This new pitch could be produced an octave lower by constructing a separate pipe two-thirds the size of the first one. If one then continued to construct pipes alternately four-thirds and two-thirds the length of the previous ones, an entire system of 12 notes could be generated, which is, with the exception of the means of creation, acoustically and proportionately in the same relation as is found in the Greek Pythagorean system. The English versions of the Chinese names for the 12 pitches seem quite fanciful; but they represent theoretically correct pitches, as do terms used in the Western traditional system, such as C or A-flat (A♭). The source of each name in the Chinese system is conjectural; but Chinese classical acousticians, like modern Western scientists, no doubt found value in creating a professional nomenclature that was divorced from everyday speech and potentially descriptive of the nature of the object. For example, the use of bell names may relate to the gradual preference for tuned bells over pipes in the music division of the courts. Names like "old purifier" and "equalizing rule" may refer to the pitch problems of the Pythagorean comma mentioned earlier.

A new interpretation of Chinese theory occurred in the late 20th century with the discovery of sets of 4th- and 5th-century tuned bells. Some of the bells produce two pitches and have the pitch names written at the two striking places. This information led to the development of a 12-pitch theory in which 5 pitches are generated in a cycle of fifths, and the 7 remaining pitches are located a major third above or below the first 4. If one starts from the Western C, the tones would appear as seen in notation II. The actual sounds produced on these ancient bells do not always match the pitch name given, but recent findings imply that it might have been possible to modulate to new pitch centres and different scales.

II

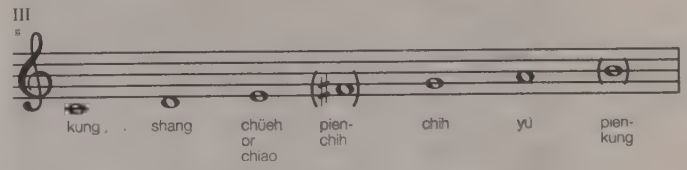


Scales and modes. For both Western and Chinese traditions, the 12 pitches are merely a tonal vocabulary from which a specific ordering of a limited number of pitches can be extracted and reproduced on different pitch levels. Such limited structures are called a scale. With a set scale it is possible to emphasize different notes in such a way that they seem to be the pitch centre. Such variations of pitch centre within a scale are called modes. In the Western traditional systems most scales use seven tones that can be transposed and that contain modes. For example, C major (C–D–E–F–G–A–B) can be made a Dorian mode by using D as the pitch centre without changing the pitches used (D–E–F–G–A–B–C), and the whole scale and its modes can be transposed to a higher or lower pitch level (F major, E♭ major, etc.). The Chinese system concentrates in a similar way on a seven-tone scale but with a five-tone core (*wu sheng*) plus two changing (*pien*) tones, as shown in notation III.

Pitch centre and modes

The notes of a scale (a set of intervals not tied to specific pitches) are often indicated in Western music with syllables such as *do re mi*. The Chinese equivalent terms for notes in their classical scale are given in notation III. As in the Western system, modes can be constructed in Chinese music, and the scale can be transposed. From these comments it can be seen that the mythical emperor Huang-ti seems to have founded a very thorough system indeed. Throughout the Ch'in (221–206 BC) and Han (206 BC–AD 220) dynasties Imperial systems were tuned and retuned to meet Imperial and heavenly needs. As noted above, theoretical sophistications and experimentations continue on to the present day. How far back they may go in time is unknown, but in the late 20th century there have been discovered stone chimes from the 2nd millennium BC that imply by their tunings that the Chinese classical tone system tradition may actually be as ancient as the legends claim. It is a pity that the music was not equally durable.

III



Extramusical associations. Returning to the extramusical aspects of the Chinese system, one finds that the five fundamental tones are sometimes connected with the five directions or the five elements, while the 12 tones are connected by some writers with the months of the year, hours of the day, or phases of the moon. The 12 tones also can be found placed in two sets of 6 on Imperial panpipes (*pai-hsiao*) in keeping with the female-male (yin-yang) principle of Chinese metaphysics. Their placement is based on the generation of the pitches of each pipe

by its being either four-thirds larger or two-thirds smaller than the previous one, the smaller ones being female.

Classification of instruments. The Chinese talent for musical organization was by no means limited to pitches. Another important ancient system called the eight sounds (*pa yin*) was used to classify the many kinds of instruments used in Imperial orchestras. This system was based upon the material used in the construction of the instruments, the eight being stone, earth (pottery), bamboo, metal, skin, silk, wood, and gourd. The sonorous stones, ocarinas, and flutes mentioned earlier are examples from the first three categories. The bells are obvious metal examples. Another ancient member of the metal category is a large bronze drum (*t'ung-ku*), which is of special interest because of the widespread distribution of archaeological examples of it throughout Southeast Asia. Equally intriguing are the designs and sounds of the bronze head of the drum as well as the frequent statues of frogs around the rim of the head. Han dynasty military expeditions to the south report that bronze drums among southern peoples represented the spirit of rain and water and rumbled like bullfrogs. The possession of such bronze drums or later gongs was, and still is, prestigious among tribal groups in Southeast Asia.

Stringed instruments of ancient China belong to the silk class because their strings were never gut or metal but twisted silk. Drums are skin instruments, whereas percussive clappers are wood. One of the most enjoyable members of the wooden family is the *yü*, a model of a crouching tiger with a serrated ridge or set of slats along its back that were scratched by a bamboo whisk in a manner recalling the various scratched gourds of Latin American bands. The Chinese category of gourd is reserved for one of the most fascinating of the ancient instruments, the *sheng* mouth organ. Seventeen bamboo pipes are set in a gourd or sometimes in a wooden wind chest. Each pipe has a free metal reed at the end encased in the wind chest. Blowing through a mouth tube into the wind chest and closing a hole in a pipe with a finger will cause the reed to sound, and melodies or chord structures may be played. Many variants of this instrumental principle can be found in Southeast Asia, and it is not possible to know with assurance where this wind instrument first appeared. Western imitations of it are found in the reed organ and, later, in the harmonica and the accordion.

The mouth organ

Han dynasty: musical events and foreign influences. The extensive work in theory and classification in ancient times implies that there must have been an equally large amount of performance practice. Modern information on all these elements of music has suffered because of the destruction of many books and musical instruments under the order of Shih Huang-ti, emperor of the Ch'in dynasty. Yet there are several survivals from the Han dynasty that do give some insight into how the musical events took place. In the court and the Confucian temples there were two basic musical divisions: banquet music (*yen-yüeh*) and ritual music (*ya-yüeh*). Dances in the Confucian rituals were divided into military (*wu-wu*) and civil (*wen-wu*) forms. The ensembles of musicians and dancers could be quite large, and ancient listings of their content were often printed in formation patterns in a manner analogous in principle to those of football marching bands in America today. Rubbings from Han tomb tiles show more informal and apparently very lively music and dance presentations at social affairs. The early Chinese character for dance (*wu*) implies movement by the body more than by the feet. The folk sources of many of the songs from the *Shih Ching* and later books show that courtly musical life was not without its gayer and more personal and secular moments. The stringed instruments, notably the seven-stringed *ch'in* zither, apparently were popular as vehicles for solo music.

The Han dynasty empire expanded and at the same time built walls between its national core and western Asia. But these actions were paralleled by an increasing flow of foreign ideas and materials. Buddhism entered from India to China in the 1st century AD, whereas booty, goods, and ideas came from Central Asian Gandharan, Yüeh-chih, and Iranian cultures along the various desert trade routes via the cities of Khotan (Ho-t'ien) to the south (3rd through 5th century), Kucha (K'u-ch'e) in the centre (4th through 8th century), and Turfan (T'u-lu-p'an) to the north (5th through 9th century). Desert ruins and Buddhist caves from this period and later reveal a host of new musical ensembles and solo instruments. Two stringed instruments of particular interest are the angle harp (*k'ung-hu*) and the pear-shaped plucked lute (*p'i-p'a*). The harp can be traced back across Central Asia to the ancient bas-reliefs of Assyria. The lute also seems to have West Asian ancestors but is a more "contemporary" instrument. Variants of this instrument have continued to enter or be redesigned in China down to the present day. A delightful symbol of the long-term musical and commercial value of such a plucked lute is found on a 10th-century clay statue of a caravan Bactrian camel with two different styles of *p'i-p'a* tied to the saddle post on top of the rest of the cargo.

Diffusion of instruments in the Han dynasty

New percussion instruments are evident in the celestial orchestras seen in Buddhist iconography. One apparent accommodation between old Chinese and West Asian tradition is the *fang-hsiang*, a set of 16 iron slabs suspended in a wooden frame in the manner of the old sets of tuned stones. Knobless gongs related to the present-day Chinese *lo* seem to have entered the Chinese musical scene before the 6th century from South Asia, while the cymbals (*po*) may have come earlier from India via Central Asian groups. One of the most sonorous Buddhist additions was a bronze bell in the form of a basin (*ch'ing*) that, when placed rim up on a cushion and struck on the rim, produces a tone of amazing richness and duration. Among the varied new instruments pictured in heavenly ensembles, one can still find occasional "old-time" instruments such as a set of narrow wooden clappers (*ch'ung-tu*) tied together on one end like ancient wooden books. The clappers were sounded by compressing them quickly between the hands. Variants of this Chou dynasty instrument are still heard in all three major East Asian countries.

Not all the new influences in China came via religious or trade activities. During the Six Dynasties period (AD 220–589) China was rent by internal strife and border wars. The constant confrontations with the Tatars of the north caused an increased interest in the musical signals of the enemy via drums, trumpets, and double reeds. Although related instruments were equally evident to the south and west, there can be little doubt that the creation of cavalry bands with double kettledrums are direct imitations of the musical prowess of the horseback terrorists against whom the walls of China were built. With great effort and much blood, China gradually reunified under the Sui dynasty (581–618), and older courtly music and the latest musical fads were consolidated.

T'ANG DYNASTY

Thriving of foreign styles. The few centuries of T'ang dynasty existence (618–907) are supersaturated with brilliant Imperial growth and cultural flourishing as well as military and natural disasters. Such a rich loam of good and bad nourished one of the most fascinating eras of music history in the world. The more formal Imperial ceremonies revitalized the ancient orchestras of bells, stone chimes, flutes, drums, and zithers, plus large bands of courtly dancers. In reality, Imperial power was based perhaps less on the Mandate of Heaven than on the "liberation" of neighbouring countries, a development of more thorough tax systems and more and more trade cities and harbours. Into all these power sources flowed foreign goods and foreign ideas. Persians, Arabs, Indians, and Malayans were found in the foreign quarters of port towns, while every trade caravan brought in masses of new faces and modes of living. Perhaps it is not surprising that an 8th-century poet, Yüan Chen, should lament about air pollution created by western horsemen, about the ladies who studied western fashions and makeup, and about the entertainers who devoted themselves to only "western" music. (One must remember that the term western refers to the land west of the Great Wall.)

There was hardly a tavern in the capital of Ch'ang-an (now Sian, Shensi province) that could compete without the aid of a western dancing or singing girl with an ac-

Tavern entertainers

companying set of foreign musicians. Popular tunes of the period included "South India" and "Watching the Moon in Brahman Land," while beautiful, exotic dancing boys or girls were ever the rage. One set of girls from Sogdiana (centred in modern Uzbekistan) won the support of the emperor Hsüan-tsung (712–756) because they were costumed in crimson robes, green pants, and red deerskin boots and twirled on top of balls. Other girls from the area today called Tashkent inspired a poet of the 9th century, Po Chü-i, with their dance, which began with their emergence from artificial lotuses and ended with the pulling down of their blouses to show their shoulders, a style not unfamiliar to old Western burlesque connoisseurs. A study of the lithe bodies and flying sleeves on T'ang clay dancing figurines is an even more compelling proof of the style of the era. In such a context one can understand how eventually an additional character was added sometimes to the word for dance to indicate the movement of the legs as well as of the body.

In addition to all the commercial musical enterprises of the T'ang dynasty period, there was another equally extensive system under government supervision. The T'ang emperor Hsüan-tsung seemed particularly keen on music and took full advantage of the various musical "tributes" or "captives" sent to him by all the nations of Asia. This plethora of sounds was further enriched by the special area in Ch'ang-an called the Pear Garden (Li-yüan), in which hundreds of additional musicians and dancers were trained and in which the emperor himself was most active. Such trainees were often female. They followed in an earlier tradition of court girls (*kung-nü*) whose basic duties were to entertain distinguished guests.

The mass of different foreign musical styles in the capital was too much for the government musical bureaucracy. A distinction already had been made between court music (*ya-yüeh*) and common music (*su-yüeh*); but T'ang nomenclature added a third kind—foreign music (*hu-yüeh*). Eventually officials organized Imperial music into the 10 kinds of systems (*shih-pu chi*). Of these categories, one represented instrumentalists from Samarkand, whereas another group came from farther west in Bukhara (in modern Uzbekistan). Kashgar, at the mountain pass between the east and west, sent yet a different group. Musical ensembles also were presented to the emperor from the eastern Turkistan trade centres of Kucha and Turfan. India and two recently defeated kingdoms of Korea provided still other musicians. Chinese and Kucha music were blended by different musicians. One group was supposed to maintain the old styles of Chinese folk music, and there had to be one special group for the performance of formal Chinese court music. These 10 types by no means completed the picture, for nearly every Asian culture took its chance at musical goodwill in Ch'ang-an. Nothing from farther west appears in T'ang China, for culture hardly existed in Europe at that time. Nevertheless, one can sense in T'ang musical culture an internationalism not matched until the mass communications of the mid-20th century provided radio and phonograph owners with the delights of a similarly exotic and extensive choice.

Courtly music. The only music that can be discussed in a survey of a repertoire so large is the more official courtly music. Ritual presentations are generally divided into two types: so-called standing music, performed without strings and apparently in the courtyard; and sitting music, for a full ensemble played inside a palace. There are lists of the names of some pieces in these categories with their authorship usually credited to the emperor or empress of the time. For example, "The Battle Line Smashing Song" was said to be by the T'ang emperor T'ai-tsung (626–649). The accompanying dance is listed for 120 performers with spears and armour. A similarly grandiose piece is the "Music of Grand Victory" credited to the next T'ang emperor, Kao-tsung (649–683). Wu-hou (d. 705) is said to have written "The Imperial Birthday Music," in which the dancers form out the characters for "Long Live the Emperor" in the best modern marching-band tradition. Music inside the palace includes a concert version of "The Battle Line Smashing Song," with only four dancers, "A Banquet Song," and a piece supposedly composed by the empress Wu-hou in honour of her pet parrot, who frequently called out "Long live her majesty." Those familiar with music in the courts of Henry VIII and Louis XIV or with the songs always ending in praise of Queen Elizabeth I may recognize the cultural context of such music.

Courtly extravaganzas

Later-dynasty copies of T'ang paintings show ladies entertaining the emperor with ensembles of strings, winds, and percussion; and many of the choreographic plans of the larger pieces are also available in books. According to some sources, court orchestra pieces began with a prelude in free rhythm that set the mood and mode of the piece and introduced the instruments. This was followed by a slow section in a steady beat, and the piece ended in a faster tempo. Documents also tell much about the instrumentation and the colour and design of each costume of the musicians and dancers. No orchestral scores are to be found, however. One solo piece for *ch'in* survives, and 28 ritual melodies for *p'i-p'a* were discovered in the hidden library of the Buddhist caves of Tun-huang (Cave of the Thousand Buddhas), but the grand musical traditions of T'ang remain frustratingly elusive. Major clues to their actual sounds will be found in marginal survivals of such music, which will be discussed in the Korean and Japanese sections. The original traditions waned with the decline of T'ang good fortune, and the conflicts of the Five Dynasties and Ten Kingdoms period (907–960) brought the international period to an end.

SUNG AND YÜAN DYNASTIES

Consolidation of earlier trends. Despite the chaos of kingdoms in the 10th century, or perhaps because of it, cultural traditions solidified, so that by the Sung dynasty (960–1279) one can speak of a national rather than an international cultural mood. Many of the short-lived usurpers of regional governments were of "barbarian" (*i.e.*, Turkish) origin, but their general cultural efforts were to appear Chinese rather than to import further foreign fads. But one significant foreign musical addition of the period was from the northern Mongols in the form of a two-stringed fiddle, or bowed lute—the "foreign lute" (*hu-ch'in*). It became an important feature of the plebian theatre and teahouse world, which grew stronger and larger as more musicians and dancers were dropped from government payrolls. With the establishment of the Sung court, Confucian ceremonies and similar "old-fashioned" musical events were revived; but Imperial contributions to music of the period were primarily in the creation of gigantic historical or encyclopaedic works. For example, the official *Sung shih* (1345; "Sung History") contained 496 chapters, of which 17 deal directly with music, and musical events and people appear throughout the entire work. The *Yü-hai* encyclopaedia (*c.* 1267; "Sea of Jade") has 200 chapters, with 10 on music. It is interesting that the *lü* pipes are discussed separately under the topic of measurements. Manuals on how to play the seven-stringed *ch'in* zither also survive, as well as rare music collections such as the "Songs of Whitestone, the Taoist," based on the poems and songs of Chiang Kuei (1155–1221) and first printed in 1202. Many Sung poets continued to use the five- and seven-syllable-line *shih* form perfected by T'ang writers, which was believed to have been chanted to tunes strictly adhering to the word tones of the Chinese language. The singing girls (*chi-kuan*) of the teahouses and brothels and the general growth of urban, mercantile life inspired the creation of *tz'u* poems, which were free of word-tone restrictions, filled with colloquial phrases, and capable of freewheeling musical settings. A major source for music based on both the old and new forms is found in the rising world of public theatre.

Music theatre. Chinese drama can be noted as far back as the Chou dynasty, but it was really the T'ang period Pear Garden school that quite literally set the stage for Chinese opera. Regional music-drama flourished throughout the Sung empire, but the two major forms were the southern drama (*nan-ch'ü* or *nan-hsi*) and the northern drama (*tsa-chü* or *pei-ch'ü*). The *tz'u* poetical form was popular in both, although the southern style was held to be softer, with its emphasis on five-tone scales and flute and percussion accompaniments. The northern style

Northern and southern styles

is said to have preferred the seven-toned scale, to have used more strings, and in general to have been bolder in spirit. According to period writers, each of the four acts of a northern drama was set in a specific mode in which different tunes were used, interspersed with dialogue. The southern style was more lyrical.

The Mongols under Genghis Khan and later Kublai Khan finally succeeded in invading China, and the foreign Yüan dynasty (1206–1368) was founded. The two styles of drama noted above continued and intermixed under Yüan drama (*Yüan-ch'ü*), while the basic poetical form became *san-ch'ü,* popular songs of even freer style. On stage there appeared standard songs for specific situations or emotions that could be used in any opera, thus making it easier to communicate a story to mass audiences who may have spoken in many different dialects. Additional appeals to the general public were made by bringing onto the stage several forms of dancing and acrobatics, events that had been, along with several forms of puppet theatre, such gay parts of Chinese city life during the Sung dynasty.

MING AND CH'ING DYNASTIES

Internal Mongol struggles, natural disasters, and peasant revolts permitted the return of Chinese rule and the founding of the Ming dynasty (1368–1644). It in turn gave way to Manchu invasions from the north under which the last dynasty, the Ch'ing (1644–1911/12), was formed. Although there is much history and much blood involved in all such changes, one can view the music of these eras together under their two most active styles—theatre music and instrumental pieces.

Further development of opera. *Forms of the 16th–18th centuries.* The flourishing of regional music-drama has continued throughout the centuries from the Sung dynasty until the present day. Musically they vary greatly in their instrumentation and particularly in their voice qualities. However, all tend to follow a tradition of using either standard complete pieces (*lian-ch'ü*) or stereotyped melodic styles (*pan-ch'iang*) in every opera. The complete-piece approach of Yüan drama survives today primarily in a 16th-century form called *k'un-ch'ü.*

The *k'un-ch'ü* form

Nurtured in a more aristocratic form of theatre, the music of *k'un-ch'ü* was less bombastic than that of the popular theatre. The major instruments were the horizontal flute (*ti-tzu*) and the notched vertical flute (*hsiao*). The flutes often produce a special mottled tone by the presence of one hole that is covered by thin rice paper that buzzes quietly as one plays. The *sheng* mouth organ and the *p'i-p'a* plucked lute could also be found in *k'un-ch'ü,* along with a single free-reed pipe, *kuan.* The term *kuan* usually stands for one of several forms of double-reed woodwinds with cylindrical bore and no bell. Survivors of its ancient forms are found in Korean and Japanese court music. Variants of the single-reed *kuan* are found throughout Southeast Asia, where it is equally appreciated for its mellow, clarinet-like tone. A plebian instrument found in some *k'un-ch'ü* is the three-stringed plucked lute (*san-hsien*) with a snakeskin soundboard. Plucked with a bone pick, it enjoys great popularity in folk music as well as theatre music, and it developed in two sizes, the shorter one prevalent in the south and the longer one in the north. The shorter form is of particular historical interest, for it was imported into the Ryukyu Islands as the *jamisen* and from there moved to Japan, where it evolved into a samisen.

The vocal style of *k'un-ch'ü* matched the soft accompaniment and was usually performed by a male singing falsetto. Another style of opera from the same period, *i-yang ch'iang,* seemed more appealing to the general public and is noteworthy for its use at some point in its development of a chorus (*pang-ch'iang*) as well as of soloists. In addition, passages in colloquial speech were often interpolated between lines of classical poetry in order to explain them. Such lines were often sung. Still another Ming music-drama genre of considerable influence in the myriad regional forms is the clapper opera (*pang-tzu ch'iang*). In addition to the rhythmic importance of the clappers, the instrumental accompaniment of this form is noted for its emphasis on strings, the principal form being the moon guitar (*yüeh-ch'in*), a plucked lute with a large, round wooden body and four strings in double courses. An interesting addition to this instrument is the presence of a thin strip of metal tied at both ends inside the body to give the instrument a richer tone. Among the endless variants of style and accompaniments in Chinese regional opera, one must add the sounds of the extremely large flat gongs heard in the southwest and the *yang-ch'in* (western zither), particularly popular in Cantonese music. The latter is often called a butterfly harp, though it is neither a harp nor a butterfly but a hammered dulcimer derived from a Middle Eastern instrument (*santūr*) brought into China in the 18th century. Each of the myriad types of regional opera flourishing in China developed vocal styles and orchestrations that helped make it distinctive. With informed practice, listeners can still distinguish regional vocal styles, which vary from low, sensual sounds to high and nasal falsettos. For the rest of the materials concerning theatre music, it is best to turn to the primary music-drama form since the 18th century, Peking opera (*ching-hsi* or *ching-chü*).

The clapper opera

Peking opera. Credit for the beginning of Peking opera is given to actors from Anhwei appearing in Peking in the 1790s. However, Peking opera really combines elements from many different earlier forms and, like Western grand opera, can be considered to be a 19th-century product. In addition to all the instruments mentioned above, many others may be found.

The most common melodic instrument for opera is some form of fiddle, or bowed lute (*hu-ch'in*). It comes in several different forms, such as the *ching-hu* and *erh-hu.* Although the shape of the body may be different, all traditional Chinese fiddles exhibit certain specific structural characteristics. The small body has a skin or wooden soundboard and an open back. The two strings pass over a bridge and then are suspended above a pole to the pegs, which are inserted from the rear of the scroll (not from the sides as on a Western violin). Such a system places one string above the other rather than parallel to it (as on a banjo or a *p'i-p'a*). Because of this, the bow passes between the strings, playing one string by pressing down and the other by pulling up. The fingerings of tunes are done by sideways pressure, along the strings; they are too far from the pole for it to serve as a fingerboard, which, because of the vertical stringing, would be a nuisance in any case. It is this unique manner of fiddle construction that helps one determine the source of many of the bowed lutes of Southeast Asia.

Barrel drums with tacked heads (*ku*) and a double reed with a conical bore and bell (*so-na*) are used in military scenes, along with cymbals (*po*) and large flat gongs. The most common percussion instruments are a small flat gong (*lo*), a drum (*pan-ku*), and clappers (*p'ai-pan*). The small gong is some eight inches in diameter; the face is slightly curved except for a flat centre spot. It is designed in this manner in order that the tone and pitch of the gong will rise quickly each time it is hit. This "sliding" gong effect is characteristic of the Peking sound. The *pan-ku* or *tan-pi ku* is equally unique in construction. The skin is stretched over a set of wooden wedges strapped in a circle with only a small spot in the middle completely hollow. This allows the performer to produce a very dry, sharp sound. Such a tone is practical as well as aesthetic, for the *pan-ku* player is often the leader of the ensemble, and his signals are essential to the coordination of the performance. The drum player frequently plays the clapper as well, holding the clapper in his left hand while playing the drum with a narrow bamboo stick held in his right hand.

The role of rhythm

In all East Asian music one must remember that harmony and harmonic progression are not parts of traditional music. The functions of harmony—such as underlining expression, providing sonic contrast, and creating a sense of forward motion—are handled with equal efficiency by rhythm in East Asia, although the methods and sounds are very different. In both traditions, the choices are not arbitrary, and with cultural exposure one comes to recognize the musical intention, even though it is not necessary to know precisely what chord or what rhythm pattern produces an appropriate musical effect. For example, very

few listeners to Western music know that a doubly diminished chord (C–Eb–Gb–A) played tremolo means danger, although all would recognize the danger signal by ear. By the same token, a Peking opera fan hearing the large gong played alone in the rhythm

would know that the situation is a similar moment of confusion but probably would not know that the pattern is named the scattering hammer (*luan-chüeh*). Pattern names are for specialists, but pattern sounds and "meanings" are for attuned listeners. Other aspects of the functions of rhythm in East Asia will emerge in the examination of other cultures. For the moment, attention will be given to the melodic side of Peking opera.

Like any theatrical music, the tunes of Peking opera must conform to the text structure and the dramatic situation. In the latter case, one finds that a majority of Peking aria texts are based on series of couplets of 7 or 10 syllables each. Although there may be several verses set in strophic form (*i.e.*, music repeated for each strophe, or stanza), part of the musical tension is maintained by the interjection of comments or short dialogue between the two lines of each verse. These leave the listener waiting for the completion of the line. The tune aids in this forward motion and tension by playing what could be considered an incomplete melodic cadence (point of resolution) at the end of line one, which is brought to a final resolution at the end of the second line. From a dramaturgical standpoint, the arias of Peking opera can be categorized into different types whose style is recognizable in the same way that one can tell, without language ability, the mood of a love, farewell, or vengeance aria in Italian opera.

Prototypes of Peking melodies

Peking melodies themselves tend to fall into two prototypes called *hsi-p'i* and *erh-huang*. Within each of these general types there are several well-known tunes, but the word "prototype" has been used to define them, as each opera and each situation is capable of varying the basic melody greatly. The two basic identifying factors are the mode of the melody and the rhythmic style of the accompanying percussion section. In general, serious and lyrical texts are performed to an *erh-huang* melody and *hsi-p'i* tunes appear in brighter moments, though in such a large genre there are many other possibilities. Notation IV contains the string introductions to examples in the two basic types. They are transposed to the pitches of notation II for the sake of comparison. In actual performance the fiddle may be tuned lower for *erh-huang* melodies. How do the tunes differ? Both emphasize the pentatonic core and have a "changing" tone B (its pitch is actually between the Western B and B♭), but their modes differ. *Hsi-p'i* are said to emphasize (in the context of our transposition) E and A, and *erh-huang* G and C. *Hsi-p'i* melodies are often more disjunct. Although both examples are set at a standard tempo (*yüan-pan*), the *erh-huang* is faster and its rhythm denser, as it is a male aria, while the *hsi-p'i* is female and slower.

Both pieces could be played at a slower (*man-pan*) or faster (*k'uai-pan*) tempo, however, or could be accompanied by other special rhythms. Such choices often cause changes in the melody itself. In general, the choice of both tune and rhythm style is guided by the text and the character. In most arias each sentence is separated by an instrumental interlude.

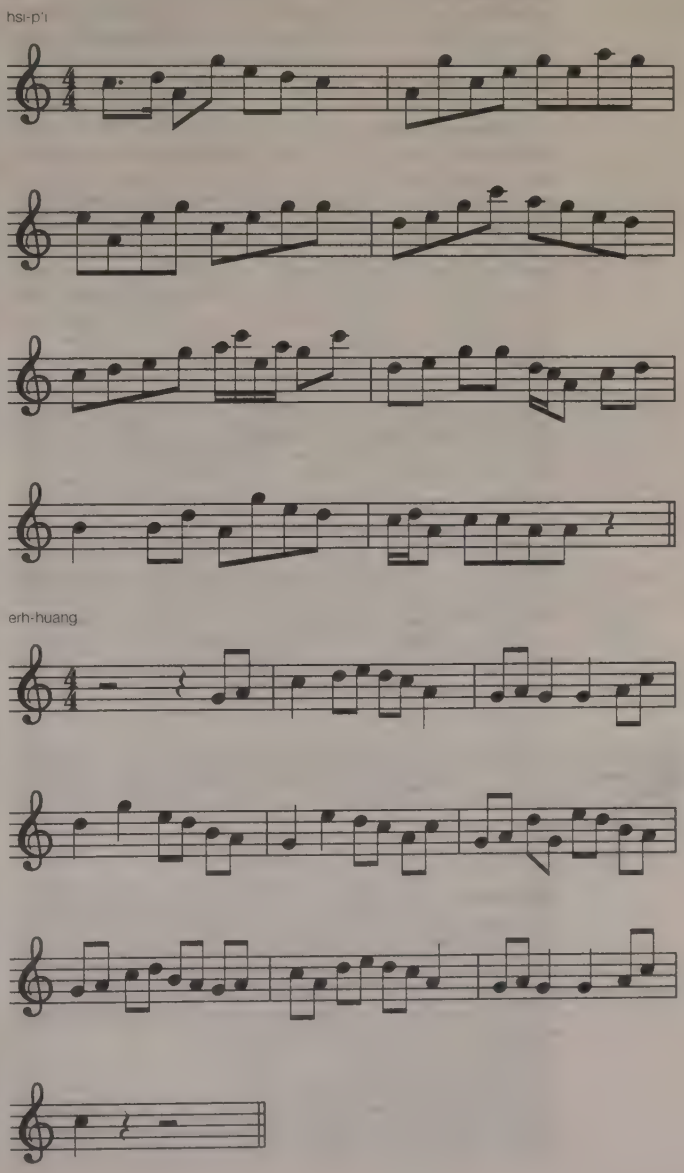
Peking opera is also characterized by colourful costumes and striking character-identifying makeup as well as acrobatic combats and dances. These conventions of Chinese opera are similar to those of 18th-century European traditions, though the sounds are certainly quite different. The need to communicate in music or in theatre requires the repeated use of aural and visual conventions if an audience is to understand and be moved by the event.

Other vocal and instrumental genres. The emphasis here has been on opera because it is best known, but there are many other popular forms from the Ming and Ch'ing periods. One is storytelling (*shuo-shu*). This tradition, which is as old as humankind and is noted in China's earliest books, continues in China in a purely narrative form, in a sung style, and in a mixture of the two. Until the advent of television and government arts control, there were narrators who recounted traditional stories in nightly or weekly segments. Their idiom was like that of surviving tellers of shorter stories. The text is usually in rhyme and is spoken in rhythm. Chinese storytellers may perform unaccompanied, but generally at least a clapper rhythm is present. One string instrument, such as a three-string *san-hsien* or four-string *p'i-p'a* lute, is also common. Songs accompanied by a drum (*ta-ku*) are the best known. The narrator not only relates the story but usually plays the clappers and a drum as well. Since the text is the core of the genre, standard melodies are used. Additional accompaniment may be provided by a string ensemble like that of opera.

Musically, the various shadow- and hand-puppet plays also are similar to the opera tradition except that, as in Southeast Asian puppetry, a manipulator must often be the singer-narrator as well.

These genres, like many regional opera forms, are often performed on temporary street stages and are eclectically creative. Saxophones and other Western instruments may combine with the ubiquitous Chinese fiddles and percussion instruments. Topical popular tunes and well-known Western music can appear among opera melodies as the drama unfolds. Recordings mix with live music so that, for

IV



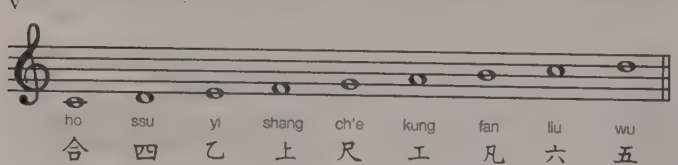
example, a battle scene may be accompanied by Chinese percussion sounds, firecrackers, and a recording of Nikolay Rimsky-Korsakov's "The Flight of the Bumble Bee."

Music for the *ch'in* zither

Leaving the many forms of vocal and theatrical music, it is appropriate to turn briefly to the instrumental. The 25-stringed *se* zither, with movable bridges, and the seven-stringed *ch'in,* with permanent upper and lower bridges (like a piano), were well known for solo music in ancient times. During the last dynasty, collections of *ch'in* music and instruction books flourished as part of certain neo-Confucian revivals. Many musical notations were developed, perhaps the most interesting variety for the *ch'in* being one in which Chinese characters were artificially constructed by combining symbols for the notes with indications of fingering technique, such as up strokes, down strokes, or harmonics. Although most of the music was based on vocal pieces or evoked some scene, there were several examples of variation forms that had an important influence on Korean and Japanese forms that followed. The *p'i-p'a* likewise developed an extensive repertoire of solo pieces, many of them quite virtuosic and pictorial. For example, anyone hearing a *p'i-p'a* battle piece needs to know very little Chinese to recognize the musical interpretations of the action. Since the mid-20th century there has been a considerable revival of solo literature for the *cheng,* a zither with 16 strings and movable bridges whose popularity spreads as far south as Vietnam. The strings are apparently influenced by the Middle Eastern dulcimer mentioned above (*yang-ch'in*), for they are metal.

Chamber music exists in many styles, functions, and locations. Some of it can be considered folk music played by farmers or working people for festivals or private entertainment, as in the American bluegrass tradition. Music of this type can still be heard at weddings or funerals in Chinese communities all over the world. During the Ming and Ch'ing periods, small ensembles of courtiers or professional musicians could be found at palaces, but the major sources for this kind of chamber music were in the world of the musically inclined businessman or trader. Because of this, certain regional forms of chamber music such as Amoy "southern pipe" and Shantung music survive in such locations as Taiwan, Manila, Singapore, and San Francisco. In this context it is noteworthy that even during Japan's isolation period from the 17th to the 19th century, Chinese vocal and chamber music, known in Japanese as *minshingaku* (Ming and Ch'ing music), was played in Nagasaki, the only open port in Japan. Examples of such dispersed regional music are of great value in the study of the oral history of Ming and Ch'ing music and of the distribution and development of various musical instruments. Much of the repertoire of such stylistic groups is derived from theatre music, but there are many examples that may imply the sounds of older lost traditions. There are a variety of notation systems, particularly for the solo music. The one most commonly used in tune books of the last dynasties is *kung ch'e,* which indicates notes in a scale as shown in notation V. This system is still popularly used, although mainland sources prefer the number system shown in the first line of notation VI.

V

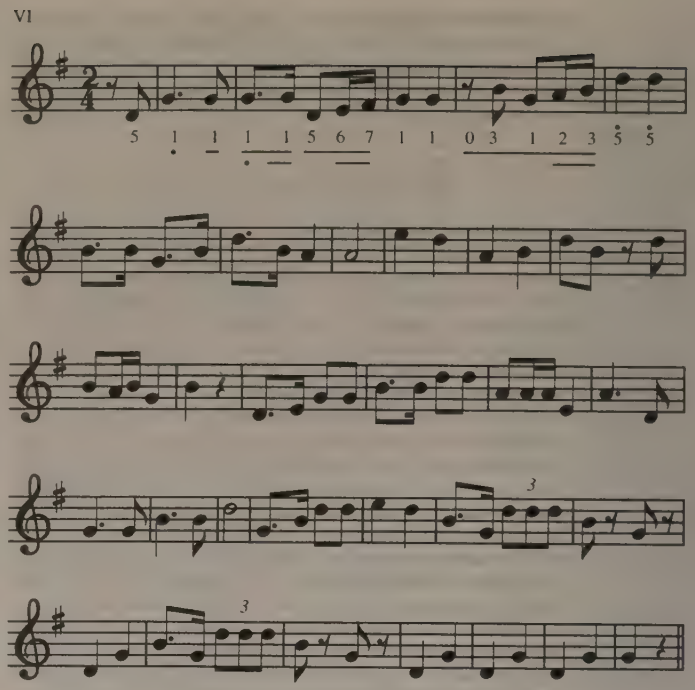


It is based on the 19th-century French *chevé* system (which used numerals 1–7 for the notes of the scale) and, unlike other Chinese notations, shows rhythm by the use of dots and beams borrowed from Western 8th and 16th notes. Percussion accompaniments also can be found in a similar style, as can larger ensemble scores, but both are more characteristic of 20th-century China.

DEVELOPMENTS SINCE 1911

Period of the Republic of China and the Sino-Japanese War. Under the influence of missionary and modernization movements, many musical experimentations occurred in the last dynasty, but these were greatly increased by the rise of the first republic in 1911 and the establishment of communist rule in 1949. During the period of the republic and of the Japanese war, a plethora of new songs were created in "modern" style, the most famous being shown in notation VI. The piece, "March of the Volunteers," was written in 1934 by Nie Er (Nieh Erh) to text by the modern Chinese playwright Tian Han (T'ien Han) as a patriotic march and was adopted as the national anthem in 1949. It is an excellent example of a mixture of new and traditional Chinese music. The first phrase implies a major mode with its use of F♯. However, after that point the entire piece is Chinese pentatonic. The first phrase also leads one to expect symmetrical four-bar phrases, but the tune quickly takes a more flexible Chinese course. Chinese and Western composers continued to try out bits of each other's traditions with only occasional success, and individual Chinese artists have become famous for their performance on Western instruments. Chinese instruments in turn have been subjected to many modernizations, such as the building of a family of *erh-hu* fiddles by the creation of bass and alto versions. In conjunction with this movement there was the appearance of concerti for such instruments accompanied by a mixed Western and Chinese orchestra.

VI



The "modern" style

Communist period. As was noted earlier, many completely traditional forms continued, particularly in foreign Chinese communities. The special point of interest since 1949, however, is the application of Marxist doctrine to the musical scene of China. The first obvious area of change is found in the ever popular forms of regional and Peking opera. Although the appeal of traditional tales of emperors, princesses, or mythological characters could not be suppressed, the emphasis of all new operas was on workers, peasants, soldiers, and socialism. Thus, *San-kuo chih yen-i* (*Romance of the Three Kingdoms*) or *K'ung-ch'eng chi* (*The Ruse of an Empty City*) tend to be replaced by *Qixi Baihutuan* (*Ch'i-hsi Pai-hu t'uan; Raid on the White Tiger Regiment*) or *Honghu chiwei dui* (*Hung Hu ch'ih-wei t'ui; Red Guards of Hung Lake*). Aria topics also vary, such as "Looking Forward to the Liberation of the Working People of the World" or "Socialism Is Good."

As part of the encouragement of people's music, the national government emphasized regional folk music. Provincial and national research institutes were created to collect and study such music, and folk songs were incorporated into primary as well as advanced and Western music education. In general, folk music was "reconstructed" away from its former individualistic nature into collectives

of choruses or folk orchestras. The topics of such regional songs also were reconstructed so that they reflected the new socialist life. The most famous new folk song from Shensi province is "Red Is the East," while the Miao people were credited with "Sing in Praise of Chairman Mao." During the Maoist period, more than 50 minority groups and provincial Chinese ensembles had at least one song directly in praise of Chairman Mao, while other songs dealt with local industries and accomplishments. Such songs are sometimes performed in regional style with traditional accompaniments, although they may often be found arranged Western-style for use in the public schools of the nation. This effort, in addition to the number of recordings that are available, make it possible for a Chinese citizen to become aware, perhaps for the first time in history, of the great variety of local music traditions in his large country, even though such music appears now in Marxist reconstructions. Marxist defense of this changed folk music is that music of a given period must reflect the views and aspirations of the masses (as understood by the government) and must be based on idioms of the people. Composers of concert music have produced many folk orchestra compositions along with symphony, piano, and military band music based on this basic Marxist musical principle, called Socialist Realism. When dealing with traditional instruments and vocal styles, the composers have sometimes created extremely original and interesting pieces despite the general conservatism of government aesthetics policies. Vocal and choral music are preferred because of their ability to communicate specific national goals more efficiently than, for example, *The Sacred War Symphony*.

Socialist Realism

It must be remembered that music exists in a cultural context and that it has never remained static since the world began. In the late 20th century, music of all periods from every society is available to those with sufficient mass communication sources. Exchanges have been made between Western and Chinese ensembles and musicians, and audiocassettes and radio broadcasts cannot be easily silenced. Euro-American music is part of China's urban culture, and new socialist messages can be heard in Western-style popular music settings. At the same time, tentative efforts have been made to use contemporary Western idioms in Chinese concert music. It does seem unlikely that the tuning of the *lü* pipes for rulers will ever be a major concern of Chinese musicians again, but the ability of China to preserve so many historical facts, materials, and idioms along with modern changes is sufficient to keep the musical world in awe for some centuries to come.

The music of Korea

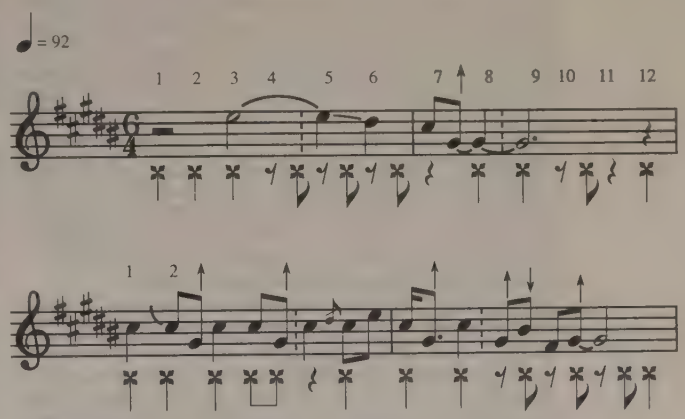
On a map Korea looks like a finger pointing from the top of China down to the lower part of Japan. Thus, one would expect its music to reflect its "bridge" position between two such powerful traditions. The movements of foreign, particularly Chinese, armies and cultures are indeed major factors in Korea's tradition. But beneath these reflections lies a deeper core of indigenous musical styles that, at first hearing, seem most strange to the ear of listeners with preconceived notions as to what East Asian music sounds like. A possible additional factor in the growth of Korean music is the country's position as a peninsula jutting out from Manchuria and from the spawning ground of many Mongolian hordes. Archaeological sources indicate that various Mongol peoples from northern Asia did indeed occupy areas of Korea from at least 2000 BC, and Chinese writings show that their people and armies were active in Korea from the period of the Chinese Han dynasty (206 BC–AD 220) on. Obviously, a study of Korean music contains riches extending far beyond its geographic borders.

SHAMAN MUSIC

The earliest references to music in Korea are found in a 3rd-century-AD Chinese history book that comments about agricultural festivals (*nong-ak*) with singing and dancing among the tribes of northwestern Korea. Such events are still a strong part of Korean life. Another ancient but long-lived tradition in Korea is shamanism, or communication with the unseen world by medicine men in a state of trance. This is of special interest because such a belief is characteristic not only of all northern Asian tribes but also of other peoples (such as Eskimos) who live in the northernmost regions of the world. Korea is one of the few countries south of the Arctic area that maintain strong shamanism in the face of several foreign religious adoptions such as Buddhism, Confucianism, and Christianity. A few Korean shamanistic events, however, show still other possible prehistoric connections. For example, sometimes the head of an animal may be placed in the centre of a Korean ritual ground, and mythology says that the first ruler of Korea was created by the union of god and a bear. Divine origin is part of Japan's Imperial mythology, and the head of a bear is central to the important rites of the Ainu tribal culture in northern Japan.

Today, a female Korean shaman (*mudang*) may use many combinations of musical instruments. The simplest and potentially most significant accompaniment is a small, flat gong with a slight rim. It brings to mind the single-headed pan drum with a wooden or bone hoop found in the shamanism of most of Central Asia and in the Arctic Circle as far away as Lapland and Hudson Bay. A drum sound itself is produced in Korea by the most popular percussion instrument, the *changgo*, an hourglass-shaped, two-headed drum struck by the hand on the left head and a stick on the other. In Korean shaman rituals flutes, double reeds, fiddles, and other gongs and drums may be used that at first sight may appear rather Chinese. The sound, however, creates a totally different impression.

VII



The music shown in notation VII represents a flute and gong excerpt from a shaman ensemble that also contains a drum, zither, fiddle, and oboe in a driving polyphony (combination of simultaneous voices, or parts) that seems closer to Dixieland jazz than to Chinese music. The flute tune, with its microtonal slides, its use of a fourth (c♯″-g♯′) "out of tune" with the Chinese *lü* pipes, and its rhythm, produce a very un-Chinese, jazzlike sound. The style is totally traditional and is notated to show the special Korean proclivity for a 6-beat unit, which in this excerpt is particularly strong in the accompaniment of the other instruments. The dotted bar lines in the transcription imply a kind of polymetric syncopation that often gives Korean folk and popular music its special appeal. One part seems to be in 4 whereas others are in 6, so that they come together only after 12 beats. Triplets and even 5-beat forms are found as well. Thus, it is evident from a brief look at one example from one type of Korean shaman music, in addition to a discussion of other forms and characteristics, that Korean cultural materials continue to reflect fascinating mixtures and mysteries. The total style cannot be called purely Chinese or northern Asian but simply Korean. The characteristics of the first example are typical of the kind of music best known and loved by the general Korean populace. Studies in Korean music, however, have tended to concentrate on the less familiar styles of court music, which are maintained by dedicated national music institutes and Korean scholarship.

Polyphony, tuning, and rhythm

COURT INSTRUMENTAL MUSIC

According to legend the Three Kingdoms of Koguryŏ in the north, Paekche in the southwest, and Silla in the southeast were established in the century before AD 1 along with a small Japanese-related enclave (Kaya; Japanese: Mimana). The subsequent organization of courts and the introduction of Chinese religions resulted in an ever-increasing importation of Chinese musical materials. Indications of this can be found in such sources as paintings in an AD 357 tomb near An-ag, a colony of China at that time. A horseback band of the Chinese Han dynasty style is seen with drums and a small bell hit with a hammer. One brave rider apparently is able to play the Chinese panpipes in transit. Deeper in the tomb a zither, a lute, and a very long end-blown flute can be seen accompanying a dancer whose long nose and costume imply that Central Asian traditions may have traveled even as far as Korea by the 4th century. The Silla dynasty domination (668–935) coincided closely with the heyday of the Chinese T'ang period, and the subsequent Koryŏ (935–1392) and Chosŏn (Yi) dynasties (1392–1910) also tended to match parallel Chinese periods. Thus, Korea's court-music traditions tended to reflect those of China.

Survivals of ancient Chinese music

Being on the border of Chinese culture, Korea was able to maintain certain ancient traditions during periods of barbarian domination in China proper. Such marginal survivals are of particular importance because many have continued to the present day, thus giving extremely rare examples of music traditions long gone from the land of their origin. For example, in the Silla period, court music was divided into *hyang-ak,* Korean music; *t'ang-ak,* T'ang and Sung Chinese music; and *a-ak,* Confucian ritual music. The instruments used for these ensembles were those described earlier in the discussion of Chinese music, such as sets of tuned stones (in Korean *p'yŏn-gyŏng*) and bells (*p'yŏnjong*), mouth organ (*saeng*), and instruments in all the other eight categories of Chinese classical traditions (*e.g.,* those based on the materials used in their construction; see above). Unlike China, ensembles using such instruments can still be heard in the national institutes of North and South Korea and in Confucian rituals. Among the many instrumental treasures still played in Korea is the *ajaeng,* a zither—with seven strings and movable bridges—that is not plucked but, more remarkably, is bowed with a rosined stick of wood.

The globular flute (*hun*), mentioned as one of the very earliest artifacts of Chinese music, has been played in Korean Confucian temples since the 12th century, as has a *chi* flute, which has a bamboo mouthpiece plugged into the mouth-hole with wax. In addition to five finger holes it has a cross-shaped hole in what on other flutes is the open lower end. The lower end of the *chi* can thus be closed by the little finger of the left hand. This unique flute is known to have been in Korea by at least the 11th century and, like the previous two examples, has totally disappeared from the rest of East Asia. By contrast, the *p'iri* cylindrical double reed aerophone (wind instrument) has many relatives in Asia, but the rich saxophone-like tone produced by its deceptively narrow tube body and large reed are not heard elsewhere. It is heard in many other forms of Korean music, from folk festivals to party music.

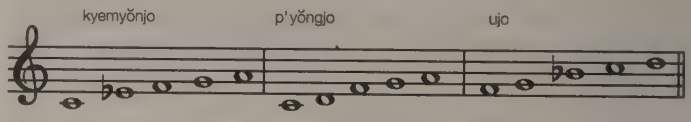
Indigenous instruments

Not all the instruments of Korea are Chinese imports. The *taegŭm* flute with six finger holes, a membrane-covered hole for a buzzing sound, and open holes near the end would seem to be a Chinese instrument, except for its spectacular length of 74 centimetres (2 feet 5 inches) and its gigantic mouth-hole. A Korean musician, Wang San-ak, is credited with the invention in the 7th century of a *kŏmungo* zither with six strings. Two strings on one side and one on the other have movable bridges, whereas the central three strings pass over 16 bridges. It is played by plucking the strings with a wooden stick. One of the other mysterious Korean instruments is the *haegŭm* two-stringed fiddle. It would seem to be an obvious relative of the Chinese equivalent, with the bow passing between the strings, except that the neck is bent toward the strings (rather than away from them, as in the rest of the world), and the pegs seem to be inserted backward, so that the strings are wrapped around the large round part of the pegs instead of the narrower end, which sticks out, unused, from the back of the neck. The *kayagŭm* board zither with 12 strings and movable bridges is surprising in sound to those accustomed to Chinese and Japanese zither melodies. It is held that the instrument was created in the 6th century in the Japanese-dominated Kaya area—thus the survival of one example in the 8th-century Japanese Shōsō-in treasure house. The *kayagŭm* is regarded as Korea's favourite native instrument, and it can be heard in all levels of Korean music and dance. The *sanjo* variation forms for this zither represent one of Korea's most famous purely instrumental genres.

Much of what is known about the origin of instruments is derived from Chinese and Korean historical books and administrative documents, such as the grand list of presents sent by the Chinese Sung emperor to Korea in the year 1111. The list includes 10 sets of stone chimes and 10 bell sets, along with 5 iron equivalents and numerous other instruments. Korean musicians performed successfully at the Chinese court, and Korean monks attended the international training centres in China to learn Buddhist chant. During the reign of Sejong (1419–50), new Imperial shrine music and traditional Confucian ritual music were emphasized along with musical settings of epics written in the newly developed Korean alphabet. The grand traditions of China were preserved under the guidance of the court master of music, Pak Yŏn (1378–1458).

Proof of the diligence and concern of these and later efforts are found in the *Akhak kwebon* ("Music Handbook"), first appearing in 1493. The nine volumes of this work contain pictures of all the court instruments along with their fingerings or tunings, costumes and accessories for ritual dances, and the arrangements of dance designs and orchestral seatings. The first three volumes deal with music theory and contain ample evidence of the continuation of the complete Chinese classical tradition discussed earlier. The only differences are the pronunciations given to the Chinese characters in which the terminology is written. Over the centuries the naming and interpretation of the pentatonic scales in Korea have varied greatly. Today *kyemyŏnjo* and *p'yŏngjo* are considered basic. *Ujo* is a variant on *p'yŏngjo,* usually a fourth higher. The exact pitch on which these modes are written or played varies. They are based on C in notation VIII for comparison with notation III.

VIII



Balance of Korean and Chinese traditions

From the short theoretical discussion above it should be evident that Korean musicians maintained a balance between native and Chinese traditions. Such a balance is seen in the standard instrumentation of the three major court orchestras. By the 15th century the Chinese-style *t'ang-ak* and the Confucian *a-ak* ensembles concentrated on Chinese instruments such as bell and stone chime sets, and the texts of surviving *t'ang-ak* pieces such as *Loyang-chun* ("Spring in Loyang") follow the Chinese *tz'u* poetical form. Processional military music (*chui-ta*) begins in the style seen in ancient drawings, with drums, gongs, and accompanying conch shell and straight trumpets, in addition to a "barbarian" oboe with a conical body. This ensemble is followed by a softer one with the more typical Korean hourglass drum (*changgo*) and cylindrical oboe (*p'iri*), the unusual Korean fiddle (*haegŭm*), and flutes (*taegŭm*). The softer ensemble can also be heard in dance music (*samhyŏn*), whereas chamber music (*chŏng-ak*) softens this group further by using a smaller oboe along with the later addition of the Chinese "western" dulcimer (*yang ch'in,* or, in Korean, *yang-gŭm*). The most famous suite of movements in this and in orchestral traditions is the *Yŏngsan hoesang,* which consists of 9 to 11 pieces taking some 30 minutes to play. The title is based on a former religious chant about the Buddha preaching on Mount Yŏngsan, but the pieces attached to this general name have since lost their vocal tradition. When the Korean ensem-

ble (*hyang-ak*) plays pieces like *Sujech'ŏn* ("Long Life as Immeasurable as the Sky"), one hears a more indigenous combination of the hourglass drum, oboes, flutes, fiddles, and the special bowed zithers (*ajaeng*). Although the style is still slow and "ancient," the sounds seem less Chinese.

The survival of so many old traditions is partly due to the preservation of notation books. Many are in the traditional Chinese forms. In the late 15th century, however, a Korean mensural system (*i.e.*, a notation showing time values) was created that, through the use of columns of 16 squares, gave a clearer indication of rhythm and tempos than do most Chinese notations. This system, usually with modifications into 6- or 12-square groups, is used today to notate the six-beat rhythms and can be read as easily as Western notation if one can read Korean.

VOCAL MUSIC

Vocal music is another important side of the Korean tradition. One of the longest and rarest older forms is the *kagok*, which consists of 26 five-line solo songs and one duet. Accompaniments and interludes are provided by a small ensemble. *Sijo* is a classical three-line form of Korean poetry that also can be sung to the accompaniment of the hourglass drum. Narrative songs are found in the genre called *kasa* accompanied by a flute and drum.

Kagok, *sijo*, and *kasa* are all types of court music. The dominant narrative form of music performed today, however, is the folk genre *p'ansori*. It is traditionally performed by a singer-narrator (*kwangdae*) and a drummer (*kosu*), who marks phrases with rhythmic patterns on a barrel drum (*puk*) and with vocal interjections (*chuimsae*). Spoken narration and dialogue (*aniri*) are balanced with songs (*chang*), body movements, and fan gestures as hours of epic drama unfold. It may be that *p'ansori* emerged from ancient shamanistic entertainments of the gods before it became popular with the aristocracy. The earliest written records of it date to 1775. Of the many stories noted in later sources, five have survived both in written form and in popular folk tales. In the late 20th century, government support revived the tradition, so that *p'ansori* epics are available on recordings and in professional performances.

P'ansori

MODERN MUSIC

During the period of Japanese occupation (1910–45), indigenous arts were suppressed and Western music dominated the education system. As in Japan, this dominance continues, and Korean skills in Western music performance have earned international recognition. Since World War II, the support of national arts in Korea has created many new tradition-based musics. Those in North Korea follow the Chinese pattern discussed earlier, while the South generally follows Western contemporary trends.

The music of Japan

As has been noted, Japanese music can be considered a national tradition set in the satellite category of the general East Asian music culture. Korea served as a bridge to Japan for many Chinese musical ideas as well as exerting influence through its own forms of court music. A comment has been made as well about the presence of northern Asian tribal traditions in Japan in the form of Ainu culture surviving on Hokkaido island. It should further be pointed out that the island isolation of Japan allowed it to develop its own special characteristics without the intense influences of the Chinese giant and the Mongols so evident in other mainland cultures. Therefore, in the ensuing discussion all the "foreign" elements will be placed in the matrix of traditions and styles that are characteristically Japanese.

MUSIC BEFORE AND THROUGH THE NARA PERIOD

Early evidence. As in the case of the history of mainland traditions, ancient Chinese sources and modern archaeological data provide the earliest surviving insights into Japanese music. Archaeologists have discovered materials of Neolithic people in Japan and pottery remains of the so-called Jōmon culture dating back as far as the 5th millennium BC. Among the items recovered from the subsequent Yayoi period (3rd century BC–3rd century AD), the musically most significant finds are *dōtaku* bronze bells. They show that the native population had adopted Chinese metallurgy. The shape of the bells and the locations of their remains indicate that they may have entered the Japanese islands with tribes migrating from northern Asia.

Archaeological evidence

The gradual domination in Japan of one group called the Yamato clan became more evident in the Tumulus period (*c.* AD 250–*c.* 500) and led to the present Imperial system. Specific evidence of its musical life is found first in certain tomb figurines (*haniwa*), which were substitutes for the earlier Asian tradition of human sacrifices at the death of a leader. One *haniwa* has been found playing a barrel drum with a stick, while another figure is seated with a four- or five-stringed board zither across his lap. Crotal bells (pellet or jingle bells) are found on costumes, and some statues seem to be of singers. The zither is of special interest, for it is related to the Korean *kayagŭm* mentioned earlier as appearing in the Japanese section of Korea (Kaya) by at least the 6th century. It also may be the earliest example of the *wagon*, or *Yamato-goto*, a six-stringed zither with movable bridges found in Japanese Shintō music. The crotal bells survive in the form of the *suzu* bell tree, an instrument characteristic of Shintō dances only. The interpretation of another figure as a singer and the presence of a drummer are rather too general for conclusions, although a Chinese history book of the 3rd century (*Wei chih*, AD 297) does speak of the natives of Japan as singing and dancing during a funeral. This source also notes two actions well-known in Shintō today: a concern for purification and the use of hand claps in praying before a shrine.

The mention of shamanism also is found in Chinese accounts and is of particular interest to those concerned with the northern Asian aspects of Japanese culture. In this context it must be remembered that the Ainu were as populous and strong as the new Japanese people at the time of the founding of the Yamato dynasty. Battles between the Japanese and Ainu are noted in 6th-century Chinese books such as the *Sung shu* (513) and, rather like 19th-century American Indians, Ainu were found as mercenary troops in a group of Japanese forces sent to assist the Korean Silla kingdom in the 7th century. The Chinese *Sui shu* history book (630) mentions tattooed people like the Ainu, as well as a five-stringed zither and a flute. Ainu culture today maintains a Jew's harp and no flutes, but it does have a *tonkori* zither with two to five strings. It is unlike the zither on the lap of the earlier tomb figure in both its shape and playing position, being held like a banjo and played open-stringed with both hands. The surviving shamanism of the Ainu has equivalent forms in early Shintō and in a few surviving Japanese folk "mountain women" traditions. However, the guttural vocal style and the frequent polyphonic textures of modern Ainu music today seem culturally to point north rather than south or west. Perhaps the Ainu are a living link between present-day civilization and the life pictured in ancient Chinese documents.

As the Japanese people gradually drove the Ainu northward, they solidified their own internal structure and established stronger ties with continental culture. Records show that a Korean Silla (in Japanese, Shiragi) emperor sent 80 musicians to the funeral of a Japanese ruler in 453. Chinese Buddhism was officially introduced as a religion in Japan in the 6th century, selected converts being sent to China for proper training in the rituals (hence the music) of that faith. In 612 a Korean musician, Mimaji (in Japanese, Mimashi), is believed to have introduced masked dances and entertainments (*gigaku*) and southern Chinese music (*kuregaku*) into the Japanese court. Finally, by the 8th century Japan produced its own first written chronicles, the *Koji-ki* (713; "Record of Ancient Matters") and the *Nihon shoki* (720; "National History"), which recount the mythological origin of music as the form of an entertainment used by the gods to tempt the sun goddess out of her hiding in a cave (see also JAPANESE LITERATURE). Indirect references to music appear in semi-historical accounts of early court activities in the books. In addition, the *Nihon shoki* contains the texts of some

Japanese written records

200 poems, many of which seemed to have been derived from the oral musical tradition.

Predominant musical traits. It is apparent that by the 8th century the documentary history of Japanese music had begun. Although this claim predates an equal state of Western music history by some 100 years, certain interesting parallels between the two traditions can be made. Both seem more clearly established in the same general 200-year period, a short time when compared with Chinese music studies outlined above. Both developed a musical nomenclature heavily influenced by the music of religious organizations: the Roman Catholic church in the West, Buddhism in Japan. Both traditions were equally influenced by theories of a foreign culture from over the nearest sea: Greece in Italy and China in Japan. Herein many differences arise, one of the most significant being that, in the Japanese case, the foreign tradition of China at the time of its first major influence was alive and strong and could apply practical musical information and instrumentations as well as theories, whereas the Greek tradition was long dead by the same period, when the European monks turned to it for guidance. Nevertheless, one can see that the general length and beginning of each history is comparable. Before discussing Japanese music in chronological detail, an attempt should be made to envision general characteristics, realizing that in doing so the tendency is to apply aphorisms to music that stretches over a series of styles as old and varied as the music of Europe from Gregorian chant through Claude Debussy. With that caveat, general guidelines for the appreciation of Japanese traditional music can be put forth.

Aesthetic and formal ideals. These guidelines fall under three general concepts: (1) the sound ideal, (2) the structural ideal, and (3) the artistic ideal; but these three things are not clearly separate in any musical event.

In general one can say that the most common sound ideal of Japanese music is to produce the maximum effect with a minimum amount of material. For example, the *taiko* drum of the nō drama consists of a barrel-shaped body over which are lashed two cowhide heads some 20 inches in diameter stretched over iron rings. Wooden sticks are used to hit one head. Obviously, the sound potentials of the drum are many, but they are deliberately suppressed. For example, the sticks are made of very soft wood, and the strokes are applied only to a small circle of soft deerskin in the centre of the head. The *taiko,* like Japanese ink paintings, accomplishes a great deal by concentrating on very carefully chosen limitations of the medium.

Instrumental potential and tone colour

Another feature of much Japanese traditional music could be called the chamber music sound ideal. No matter how large an ensemble may be, one finds that the various instruments are set in such a way that the timbre, or tone colour, of each can be heard. This can be understood in Western chamber music and contrasts with the Western orchestral sound ideal, in which the primary intention is to merge all the instrumental sounds into one glorious colour. The colour separation of Japanese music is quite evident in the large court ensemble (gagaku), as well as in drama music and actual chamber ensembles such as the *sankyoku,* for koto (zither), samisen (plucked lute), and the end-blown *shakuhachi* flute. Such textures support the strong multilinear (as opposed to harmonic) orientation of East Asian music mentioned earlier.

The Japanese tripartite form

The structural intents of Japanese music are as varied as those of the West, but one of special interest is the frequent application of a three-part division of a melody, a section of a piece, or an entire composition. This is in contrast with the more typical two-part division of Western music. Of course, examples of both ideals can be found in the music of both cultures; the concern here is with broad generalities. The fundamental terminology of the Japanese tripartite form is *jo-ha-kyū,* the introduction, the scatterings, and the rushing toward the end. A Western musician might wish to compare this with sonata allegro form and its three parts (exposition, development, recapitulation). But the Western example relates to a complete event and involves the development of certain motives or melodic units (such as first and second theme), whereas the Japanese concept may be applied to various segments or complete pieces that are generally through-composed (*i.e.,* with new material for each segment). Japanese music reveals its logic and its forward motion not by themes but by a movement from one section to another different one until the final section is reached. Forward motion in motive Western music was often derived during the classical periods from the tension created by chord progressions. In Japanese music, such sonic events generally are not used. Nevertheless, the need for aurally recognizable patterns falling into a progression that the informed listener can anticipate is necessary in all music. In Japan such stereotyped patterns are melodic or rhythmic, not harmonic. They will be discussed in detail later; but the recognition, whether intellectual or aural, of the existence of such recurring patterns is essential to the appreciation of any music.

Word orientation. One of the artistic ideals of Japanese music is equally clear in all of East Asia. It is the tendency for much of the music to be word-oriented, either through actual sung text or through pictorial titles to instrumental pieces. With the exception of variation pieces (*danmono*) for the Japanese koto, one can seldom find a purely instrumental piece in the spirit of, for example, the Western sonata or symphony. Japanese ensemble pieces, like those mentioned earlier in China and Korea, are either dance pieces, instrumental versions of songs, or descriptive. This ideal in all of East Asia was not weakened until the late 19th century, when such music was forced to compete with Western idioms.

Guilds. By the same token, the ideal of the composer as genius, so dear to 19th- and 20th-century Western hearts, had little place in earlier East Asian music. In Japan, as in China and Korea, the names of many composers are known, but the actual setting of their music was and still is often done by a group of fairly anonymous people. One may know who was helping out at a given time and in a given place; but in any written form of the music their names, or even the name of "the" composer, may often be missing. The process might best be called communal composition. In the Orient, particularly in Japan, the performer is often the person remembered and noted. Such an ideal is understood in the West by fans of popular music. Although this ideal has given way to the Western composer "star" system in modern Japan, it does depict an important social setting for any appreciation of the older Japanese classical traditions. In keeping with this artistic ideal, one should add that often there is not one "correct" version of a given piece. Most traditional music is organized under guild systems, and thus each guild may have its "secret" version of a well-known piece. A given guild will play its version precisely the same way in each performance, for improvisation has practically no role in any of the major genres of all East Asian music. Differences are maintained between guild versions, however, in order to identify a given group's musical repertoire as separate from all the rest.

Manner of handling instruments

The separation of guild styles can be carried further to one more artistic ideal, which holds that it is not just what one plays on an instrument, it is how one plays it. For example, in the case of the *taiko* drum mentioned above, the manner in which a player sits, picks up the sticks, strikes the drum, and puts the sticks away will reveal the name of the guild to which he belongs and also can be used to judge his skill in performance. No Japanese instrument is merely played. One could almost say that its performance practice is choreographed. Such distinctions exist in the music of other East Asian cultures as well, although the clues to their understanding have not yet been revealed to outside listeners and viewers. This brief discussion of their existence in Japanese music will serve to enhance the appreciation of at least one Asian tradition as the discussion turns to a chronological study of its many styles.

The Nara period. *Codification of court music.* The previously mentioned documents from the Nara period (710–784) demonstrate how very active music was in the newly established capital in Nara. The general term for court orchestra music, gagaku, is merely a Japanese pronunciation for the same characters used in China for *ya-yüeh* and in Korea for *a-ak.* As Japan absorbed more and

more of the outside world, the music of the court, like that of T'ang dynasty China during the same general centuries, received an increasing variety of styles. In 702 these styles were organized under a music bureau (*gagakuryō*), and by the early 9th century an additional Outadokoro (Imperial Poetry Bureau) was created for handling Japanese-composed additions to the repertoire. Among foreign genres, the musical styles of the nearby Three Kingdoms of Korea have already been shown to be some of the first imports, Silla music being called in Japanese *shiragigaku*, Paekche music, *kudaragaku*, and Koguryŏ music, *kōkurigaku*. Music from the Three Kingdoms was sometimes called collectively *sankangaku*. Under all these terms were found still other Chinese and northern Asian traditions, in addition to music purported to have come from India as early as 736. Evidence of such a distant import can be found in a surviving court dance (*bugaku*) called "Genjō-raku," whose story about the exorcising of a snake can be traced to an ancient Indian Vedic tale. The date of 736 is also assumed for the entrance of music from Indochina, which survived for several centuries in a form of music called *rinyūgaku*. Although this tradition is now lost, there are extant detailed pictures of the ensemble along with other ancient instruments and a variety of dances in sources such as the 14th-century copy of the 12th-century *Shinzeigakuzu* scroll.

Influence of T'ang dynasty China. The dominant musical style of early gagaku was, naturally, from China and was called T'ang music (*tōgaku*). In Japan, as in Korea, the establishment and maintenance of such a music has made it possible for modern listeners to hear foreign versions of famous pieces long forgotten in the country of their origin. For example, there are names of pieces played and dances performed in Japan that are also found in T'ang Chinese lists. Unlike in China, however, many of these works are still played in Japan, and a few of the original costumes and masks used at that time are preserved. Perhaps the most valuable treasure in Japan for such materials from the ancient traditions of all of East Asia is the Shōsō-in, a storehouse built for the household goods of the emperor Shōmu after his death in 756. In this collection (which includes a few later additions from temples) one can find some 21 percussion instruments, 12 strings, and 12 winds, in addition to dance masks, notation, and drawings. Some of the materials are Chinese or Korean imports, while others are Japanese-made. The Chinese variant of the arched harp of the ancient Middle East (in Japanese the *kugo*) is best preserved here. The very decorations of certain instruments can also be historical gold mines. For example, the protective cover across the face of one plucked lute (*biwa*) contains the picture of a performer riding a camel near a palm-treed oasis. Another such cover depicts a group of foreign (*i.e.*, not East Asian) musicians accompanying an energetic dancer, all on the back of an elephant. Etchings along a hunting bow show scenes of dancing and music performances connected with a popular imported art of acrobatics and juggling called *sangaku*.

Instruments preserved in the Shōsō-in

THE HEIAN PERIOD

Music of the left and of the right. Further images of Japanese musical life can be captured from the Heian period (794–1185). In the very first chapter of the 10th-century *Ochikubo monogatari*, one of Japan's earliest novels, the sad fate of the heroine is noted by the fact that she was never able to learn how to play the Chinese seven-stringed *ch'in* zither, although she did have some training in Japanese koto music. The famous 11th-century works, such as Murasaki Shikibu's *Genji Monogatari* (*The Tale of Genji*), are filled with romantic koto, *biwa*, and flutes, as well as gagaku and *bugaku* performances and the singing of many songs. Diaries also show that the courtiers, now moved to Kyōto, found music to be a useful and frequent adjunct to their insular courtly life. It was in this period that the many forms of official court music were organized into two basic categories. The so-called music of the left was called *tōgaku* and contained the Chinese- and Indian-derived pieces. The music of the right was called *komagaku* and contained all Korean and Manchurian examples. In both categories there were pieces that by this time may have been Japanese arrangements or original compositions. The terms left and right were derived from the Confucian-based administration system of the new capital, which divided the entire government into such categories. In *bugaku* they controlled the costumes of the dancers, left dances emphasizing red, right dances, green. In gagaku these two major divisions standardized the instrumentation of the ensembles. When playing dance accompaniments, stringed instruments were deleted, but the two orchestras for purely instrumental performances were complete. Each used plucked 12-stringed zithers with movable bridges called *gaku-sō* or by the generic term koto. The string section was completed by a four-stringed plucked lute, the *gaku biwa*. A small hanging gong (*shōko*) and a large hanging drum (*tsuri daiko*) were found in both. The leader of a *tōgaku* piece would use a barrel drum (*kakko*) with two lashed heads struck with sticks, while a *komagaku* piece would be led by an hourglass *san no tsuzumi* drum similar to the Korean *changgo*. The standard melodic instrument for both was the double-reed *hichiriki*, with a *komabue* flute being added in *komagaku* and a *ryuteki* flute in *tōgaku*. The Japanese *shō* mouth organ appears in both.

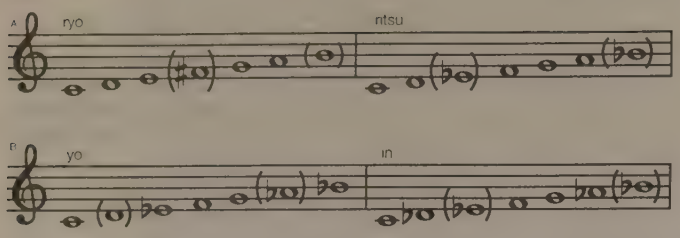
Dance costume and instrumentation

Musical notation. In modern performances the *shō* plays a fascinating cluster of harmonies, although there is some feeling that the original Chinese interpretation of its notation was melodic, with little or no harmonic addition. Part of the performance problem, outside the impressive age of the music, is that gagaku notations came only in part books, which were often rather like Western "lead sheets"; *i.e.*, they served as memory aids rather than detailed guides. For example, the *shō* notation gives only one note for every four beats of a standard piece. The modern interpretation is that each note represents the bottom of a chord, but the notes might actually have been the skeleton of a melody. The earliest surviving form of instrumental notation in Japan is a book, dated 768, of lute (*biwa*) music found in the Shōsō-in. The earliest flute part book is dated 966, and a few additional wind or string books remain from the 10th to the 13th centuries. More frequent sources can be found from the last 300 years. Scores did not exist until modern times.

The traditional part-book notations reflect the importance of oral, rote learning and the guidance of a teacher. For example, flute and *hichiriki* notations in their standard forms consist of columns first marked off by dots representing major percussion time markers (usually every four beats, though there are five- and six-beat pieces). Next, one finds a column of syllables called *shoga*, which were used to help one memorize the instrumental part by singing it. With this system it was even possible to substitute a vocal rendition of one part in an ensemble if that instrument was missing. Finally, there is another parallel column that contains a skeleton of notes or fingerings on the instrument itself. Obviously one can comprehend fully the subtle ornamentations and nuances of any melody notated in this manner only through the guidance of a teacher. In the case of the string notation, one generally finds only the names of stereotyped patterns along with occasional notes. The percussion notations likewise consist of names for stereotyped patterns. If both the strings and percussion are played as written, they appear to be merely time markers, in accordance with the colotomic principle found in much Southeast Asian and some East Asian music (the demarcation of time intervals by the entrance of specific instruments in prescribed order, a procedure contributing to the musical structure and imparting a sense of progression).

But, as in jazz, there must have been more to the music hidden in the oral tradition. Further clues as to the performance practice of this music in addition to its underlying music theory and its practical uses are found in several important sources. In 735 an ambassador, Kibi Makibi, brought back from China a 10-volume digest of musical matters (called in Japanese *Gakusho yoroku*), which implies the Chinese foundation of the art. In 1233 a court dancer, Koma Chikazane, produced another 10 volumes—the *Kyōkunshō*, describing Japanese gagaku matters. Of equal value is the *Taigenshō*, written by a

IX



gagaku musician, Toyohara Sumiaki, in 1512, when court music seemed on the verge of extinction.

Tonal system. By a combination of these sources—Buddhist music-theory tomes, part books, and present-day performance practice—it is possible to understand many of the basic principles upon which ancient Japanese music was founded. From what has already been said about the beginnings of Japanese court and religious music, it is not surprising to find that the complete tone system of both consists of the Chinese 12 tones shown in notation I, the only difference being the Japanese pronunciations of the characters for each pitch name. The scales in IX-A show that Japanese ancient music followed the East Asian tradition as well in the use of two seven-tone scales, each with a pentatonic core. The *ryo* scale (set on C for the sake of comparison) shows no great difference from the Chinese scale in III; but the *ritsu* scale seems to reveal the early presence of an indigenous Japanese tonal ideal with the placement of its half steps.

Principal tonalities

Japanese gagaku and Buddhist music theories contain most of the classical Chinese ideas concerning transpositions and modes, but in practice the two scales shown in IX-A could be constructed on only three pitches each: *ryo* on D (*ichikotsu*), G (*sōjō*), and E (*taishikī*); and *ritsu* on E (*hyōjō*), A (*ōshikī*), and B (*banshikī*). Note that the pitches for such transpositions form a classic pentatonic (D–E–G–A–B). The two names for the pitch E are present in order to make a distinction between the two scales possible on that same tone. In the unaccompanied court songs and the chants of Buddhism, one can observe the use of other transpositions, for all oral traditions in the world "adjust" notated pitches to the preferences of given singers. In gagaku instrumental music, the six tonalities are observed, part books for each instrument being organized in sections by the tonalities of the compositions. A few pieces are found in more than one tonality. A transcription of part of the basic melody for such a composition, "Etenraku," is shown in notation X-A/B. Although set in two *ritsu* tonalities (*hyōjō* and *banshikī;* X-C), it is obvious from this example that the piece, which is a "crossover" (*watashimono*), is more than merely transposed.

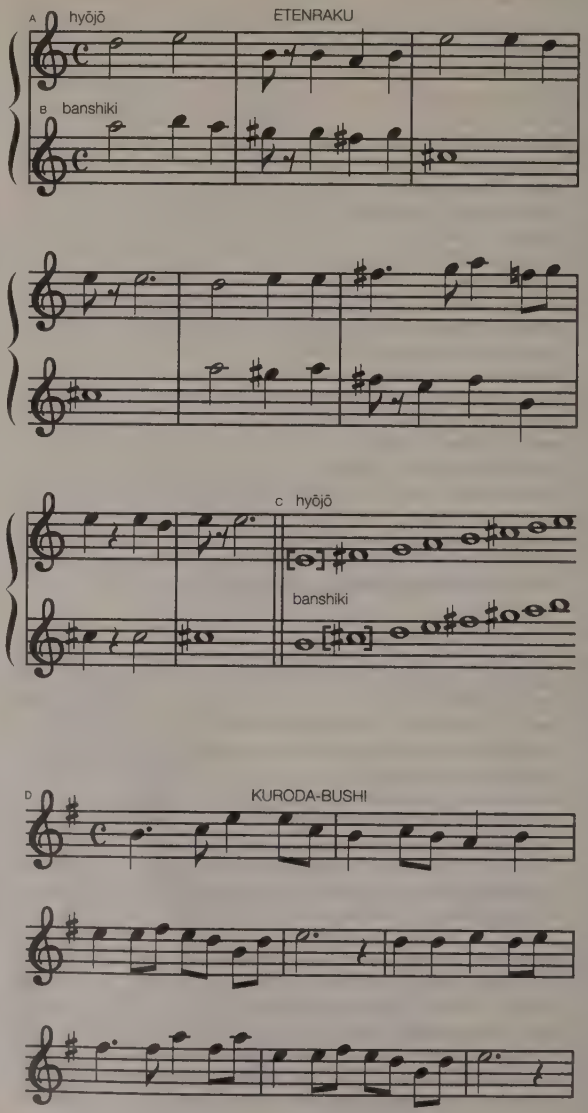
Although the scale has been transposed, yet the pitch centre of the melody also has been changed (from E to C♯). This is one of the few clear examples in performance practice of the mode systems spoken of in music theory. A glance at the related folksong "Kuroda-bushi" (X-D; see below) and at the *in* scale (IX-B) provides a preview of an emphasis on such a different mode centuries later.

Vocal music. In the poetry-oriented court life of Japan, secular vocal music would obviously be important. Many of the poems in classical collections seemed originally to have been song texts. One of the oldest secular song forms is *saibara,* which was first inspired by the singing of packtrain drivers. Among the new fads of Heian period vocal music (called collectively *eikyoku*) were *rōei,* songs based on Chinese poems or imitations of them, and *imayō,* contemporary songs in Japanese. Many gagaku melodies were given texts to become *imayō* songs, while others were derived from the style of hymns used by Buddhist missionaries. Little of these vocal traditions remains, but memories of their importance are preserved in nearly every novel and diary of the period. For larger surviving repertoires it is necessary to turn to religious music.

Shintō music. The indigenous religion of Japan, Shintō, was closely connected with the legendary legitimacy of the emperor. Thus, special Shintō music was devised for use in Imperial shrines, a tradition already familiar from the discussion of China and Korea. In Japan such Shintō music is called *kagura.* The kind of music and ritual used exclusively in the Imperial palace grounds is called *mi-kagura,* that in large Shintō shrines, *o-kagura,* and Shintō music for local shrines, *sato-kagura.* The *suzu* bell tree, mentioned before as among the earliest known Japanese instruments, is found in all such events; and the equally ancient *wagon* zither can be heard in the palace rituals and sometimes in the larger shrines.

General Shintō chanting (*norito*) is rather straightforward, whereas the surviving music of *mi-kagura* is more complex. Unison choruses of men are accompanied by the *hichiriki* oboe, a *kagura-bue* flute, the *wagon* zither, and the periodic rhythmic markings of a pair of long, thin *shaku byōshi* clappers. The music for *mi-kagura* ceremonies is divided into two types: one to praise the spirits or seek their aid (*torimono*), the other to entertain the gods (*saibari*) in the tradition, mentioned earlier, of the mythological amusements given before the sun goddess. Perhaps the most famous surviving dance suite from the Shintō tradition is *Azuma asobi* (*The Entertainment of Eastern Japan*), which can be seen as a courtly reflection of the agricultural base of Japan in its annual performances during the spring equinox and the summer solstice. The work is said to be an imitation of the dance of a heavenly maiden who performed on the beach of Suruga in the 6th century. *Azuma asobi,* along with *bugaku* dances, may be seen at many other Imperial, national, and shrine occa-

X



sions—dim but nevertheless impressive reflections of the colourful courtly life of Japan of centuries ago.

Mi-kagura is exclusively a male event, but Shintō female dancers (*miko*) are found in other shrines. Historical documents show that the Heian court, like courts in ancient China or, for that matter, all over the world, appreciated the value of female dancers and their music. In later times the Heian-originated *shirabyōshi* female dancer-musicians became important elements in the transfer of courtly and religious traditions into later theatrical forms. The major source of religious musical influence is found elsewhere in the Buddhist temples.

Buddhist music. There are many forms of Buddhist hymns, such as *saimon,* as well as semireligious dance songs, such as *goeika, nembutsu odori,* and the *bon odori* performed to folk festivals. But the basis of Buddhist classical music and hence the core of Buddhist influence on Japanese art music is found in the theory and practice of chanting known generically as *shōmyō.* Such a tradition came originally from foreign Buddhist missionaries and next from Japanese converts studying in China. Noted sources from the many Japanese interpretations of this tradition are the *Shōmyō yojinshu* by Tanchi (1163–1237) of the Tendai sect and the *Gyosan taikaishu* (1496) of the Shingon sect. The theoretical bases of these studies are similar to the ones already discussed under the topic of gagaku. Here need be added only comments about Buddhist notation systems. Most early chant notations used neumes, squigglelike signs that, like those of the early Christian traditions, served primarily as memory aids with which an initiate could recall the details of a given melody. The most influential system was the so-called *go-in hakase,* attributed to Kakui (b. 1236) of the Shingon sect. Under this method the five notes of each of three octaves of a pentatonic scale were indicated by the angle of a short line, rather like the hands on a clock. Variations of this method were of great influence in the notation of all vocal music of the period and continue to be used in Buddhist chant today.

Systems of notation

KAMAKURA, MUROMACHI, AND TOKUGAWA PERIODS

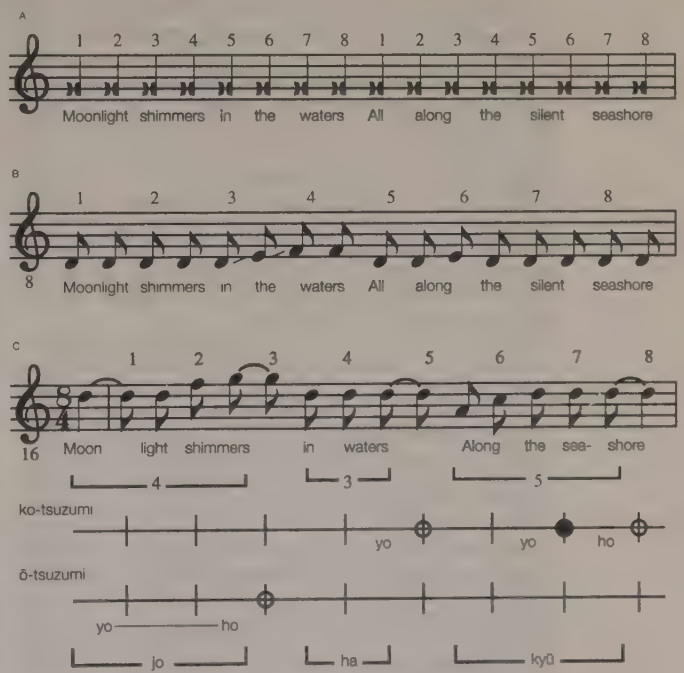
Nō music. The Kamakura period (1192–1333) marks the end of Heian court splendour and the start of a new military government located in Kamakura, far away from Kyōto. In such a context it is not surprising to find the development of long narratives of military history and the flourishing of plebian theatricals. The story of the defeat of the Heike clan (the *Heike monogatari*) was known in mansions, war camps, and temple grounds primarily as sung by *biwa*-playing bards. As in the traditions of ancient Greece and Europe, these minstrels were often blind or built their style in that of the blind-priest lute tradition (*moso biwa*) in which mendicant monks used to recite sutras (scriptures) from house to house or at temples. More lucrative forms of entertainment grew under the circus acts that developed out of the *sangaku* (folk theatricals) mentioned above; its companion comic acts, *sarugaku* (literally, monkey or mimic music); and theatricals derived from folk rice-planting dances, *dengaku.* Street parades (*fūryū*) and Buddhist entertainments (*ennen*) also were part of the colourful scene. By the subsequent Muromachi period (1338–1573) the terms *sarugaku-no-Nō* and *dengaku-no-Nō* had become the dominant terms for temple and shrine pantomime and dialogue dramas, while the comic interludes of such plays were called *kyōgen.* Through the support of the military rulers and the efforts of individual artists such as Kan'ami (1333–84) and his son, Zeami (1363–1443), the first major form of Japanese theatre developed. It became known eventually as nō (see below *Dance and theatre: The development of dance and theatre in the East Asian nations*).

The music of nō as it is performed today consists of vocal music (*yōkyoku*) with an instrumental ensemble known collectively as the *hayashi.* The singing is done by the actors or by a unison chorus (*jiutai*). The four instruments of the *hayashi* are a flute (*Nō-kan*), the *taiko* stick drum described earlier, a small hourglass drum (*ko-tsuzumi*) held on the right shoulder, and a larger one (*ō-tsuzumi*) placed at the left hip.

Melodic principles. The writings of Zeami, such as the *Kaden-sho,* contain terms reflecting the traditional tone systems and terminologies of former times. A distinction was made between the recitative section (*kotoba* or *serifu*) of a play and melodic parts (*fushi*). The melodies of nō can be categorized into two basic styles, the strong (*tsuyogin*) and the lyric (*yowagin*). Their differences are most evident in the placement of fundamental tones and the use of auxiliary tones around them. In the lyric style the three basic tones (*jō, chū,* and *ge*) are a fourth apart (see notation XI-C). The movement to and from each note is regulated in a manner comparable to the regulated approach to certain intervals in 16th-century Western counterpoint. Similar but different laws are applied to the strong style, the fundamental tones of which are much closer, the standard procedure today being that *jō* and *chū* are one pitch and *ge* is approximately a minor third below (XI-B). Melodies contain various formulas and ornamentations the names of which often reflect earlier traditions in Buddhist chant and court secular songs. The choice of combinations depends on the musical needs of the given dramatic text as well as the position of the music in the general form of the piece. Once more, such restrictions in an "exotic" music should seem reasonable to students of Western art music with its needs for stylistic restraints. The notation of nō singing (sometimes called *utai*) is derived from simpler Buddhist and early *biwa* forms that used teardrop-shaped neumes along with important pitch names to remind singers of the performance practice of a given passage. This so-called sesame-seed notation (*gomaten*) remains basic to nō vocal music today, and there are many detailed books in modern Japanese to help the initiate follow the music with the aid of a teacher. Variations in notation style and in the interpretation of specific passages are maintained by the various schools of nō along with the "secret piece" tradition basic to much of Japanese traditional music since its beginnings.

Fundamental and auxiliary tones

XI



Song types. The musical-dramatic form of nō has as many variations as any other creative genre, such as an opera or a symphony. Table 1 shows the outline of the form of one play, *Yumi Yawata* ("The Bow at the Hachiman Shrine"). In it one can see the manner in which the concept of *jo-ha-kyū,* or tripartite form, is applied in the context of sections (*dan*) along with typical placements of nō musical styles within such a form. The *shidai* is usually an introduction, and the *na-nori* allows the first character to identify himself. The traveling song (*michiyuki*) is followed by a song emphasizing higher tones (*ageuta*). Songs

Table 1: Tripartite Form Concept (*Jo-ha-kyū*) in the Nō Drama *Yumi Yawata*

sections (*dan*)	placement of musical styles
Jo (*mae-dan*)	*shidai na-nori michiyuki* (*ageuta*)
Ha	
First *dan*	*issei sashi sageuta ageuta*
Second *dan*	*kotoba sashi ageuta kotoba*
Third *dan*	*kuri sashi kuse rongi*
Kyū (*ato-dan*)	*ageuta deha sashi issei mai rongi kiri*

with lower melodic emphasis (*sageuta*) and other styles (*issei, kuri,* and *rongi*) mix with more recitative sections (*sashi, kotoba*) and with entrances (*deha*), closings (*kiri*), and dances (*kuse* and *mai*).

Within each of these sections and subsections one must remember that drama and text have their influence as well. Although the drama is not all poetic, the earlier discussion of Chinese theatre should prepare one for the fact that many lines of the text are indeed actually poems or are influenced by poetic form. Although there is great variety in the syllable lengths and combinations, the most common divisions in nō are into lines of 7 or 5 syllables. Such a 12-syllable line has been constructed in English in notation XI along with a 16-syllable variant so that the reader can compare certain basic principles in the settings of Japanese nō texts. The placement of a text rhythmically can be done in three major ways: *o-nori,* with 1 syllable per beat (XI-A); *chū-nori,* with 2 syllables per beat (XI-B); and *hira-nori,* in which 12 syllables are worked into an eight-beat frame (XI-C). The setting shown in XI-A is in the spoken (*kotoba*) style, XI-B, in the strong (*tsuyogin*) singing, and XI-C is lyric (*yowagin*).

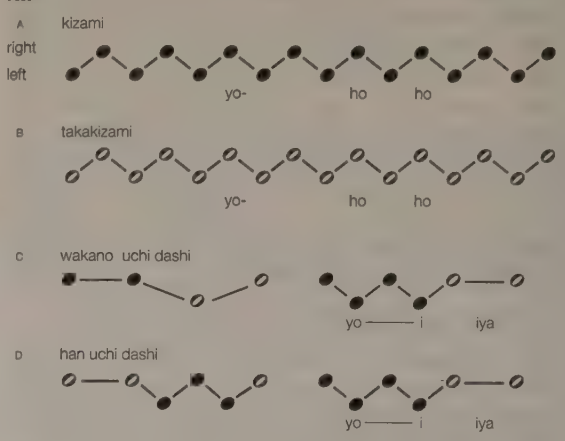
Setting of texts

Note in XI-C that, although there are two sections of 7 and 5 syllables, the actual division of their presentation (4 + 3 + 5) is tripartite—*i.e.,* in the form of *jo, ha,* and *kyū.* Lines of greater numbers of syllables in *hira-nori* require more beats, and 12-syllable lines themselves can be handled in many other ways. Thus, one must not take this artificial example to be representative of the only style of nō text setting any more than one can consider a given eight-beat phrase from one Mozart opera as being sufficient to show all there is to aria form. Nevertheless, the settings given in notation XI show in their syllable displacements and melodic contours that such "Oriental" music, like that of all cultures, does have a thorough internal logic. Nō music shares with Western art music the extra convenience of a complete written music theory, of which this short example demonstrates only a few elementary principles. The principles may be taken one step further by constructing a typical drum accompaniment for the *hira-nori* version of the texts.

Function of drum patterns. The lower portion of XI-C represents one possible setting of the text by the music of the two *tsuzumi* drums. The music of the nō drums consists of a series of named, stereotyped patterns that are aurally perceivable and that tend to progress in given orders. The pattern supporting the vocal line in XI-C is called in both drum parts *mitsuji,* although they do not always play a pattern with the same name. The circles represent moments in which the drum is struck, and the words are drum calls (*kakegoe*) uttered by the drummers. These calls are as essential to the performance and recognition of a given pattern as are the drum sounds themselves. They help to give each pattern a unique aural image. Also, the manner in which the calls are performed by the player helps to signal and control the timing of each beat in a music that is often very elastic in rhythm. Note in addition that, in XI-C, the first call of each drummer builds up to his first actual striking of the drum, which in turn marks the divisions between the three parts—*i.e.,* the *jo, ha,* and *kyū* phrasing of the vocal line. In actual performance the spacing of the beats in the vocal line may not be even with those of the drums, though beats 3 and 5 often match. The controlled but subtly varied relations of song to rhythmic accompaniment in nō drama are analogous to harmonization in Western music.

This point may be taken one step further by showing (in notation XII) a set of named patterns for the *taiko* stick drum, an instrument used only in dance sections of a play. Placement of the dots shows right- and left-hand strokes; black dots indicate the softer—and light dots the louder—strokes. The few patterns (*tetsuke*) in the example are from a set of 59 found in a *taiko* instruction book. A study of them shows that they belong to families (*tegumi;* the *kizami* family in A and B and the *uchi dashi* group in C and D). Once more the principles of harmony in Western music come to mind; *i.e.,* a C-major and C-minor chord are related because they share some common aural traits (the tones C and G in this case). If one looks into a lesson book of *taiko* music, one will find that, as in many Western harmony books, the student will be told what patterns may appear before or after each item. In Western music one learns in a similar way that certain chords may be preceded and followed by others. In both the Japanese and Western cases there is a selection of permissible choices of earlier or following events for each pattern. Thus, it would seem that the concept of prediction and anticipation is fundamental to the listener's sense of logical progression in the music of both. The major difference in this case is that the aurally perceivable, named, stereotyped pattern of Western traditional music is a vertical sonority called a chord, whereas in nō music it is a horizontal time unit called a *tetsuke.*

XII



Role of the flute. The music of the nō flute (*nō-kan*) has many stereotyped patterns, but it functions in rather different ways from the drums of the *hayashi.* Although it seems originally to have related to the vocal line, today it does not play the singer's melodies. The nō flute looks like the *ryuteki* flute of gagaku; but a short cylinder has been inserted inside its tube so that the upper holes of the flute overblow a seventh (as A–G) rather than the octave, as with all other flutes. This unique characteristic of the flute seems to reflect the tonal principles of nō mentioned earlier, whose basic notes outline a seventh (A–D–G in notation XI-C). The flute may give a specific pitch to set the tonality of a vocal entrance, but its normal functions today are to signal sections of the form and to play one of the dozen standard dance pieces used in various nō dramas. The dance pieces are set in sections (*dan*). Each piece is learned by rote or by a notation consisting of flute mnemonics placed in a frame of eight squares representing beats in a manner rather like the Korean notation mentioned earlier. The flute's seven holes are fingered by the middle joint of the fingers instead of the tips, producing an impressively fluid melody that would not fit into the graphic notation system of traditional Western music. At the same time, it does not compete with the nō vocal line by being too melodically clear. Indeed, a discussion of the nō flute seems to be a particularly appropriate finale in this brief survey of nō music (*nō-gaku*); for it shows that the form of each musical item—whether performance practice, pitch relations, structure, or notation—follows the needs of its functions. The music of nō drama seems on first hearing to be one of the most puzzling of East Asia's exotic sounds, but a study of its principles can make it become as reasonable and as beautiful as a Bach cantata.

Koto music. *Schools and genres.* The 13-stringed zither with movable bridges called the koto has been mentioned as one of the basic instruments of the court ensembles as well as a common cultural accoutrement for court ladies. The development of independent solo and chamber music genres for this instrument becomes more evident as one moves into the Muromachi period. The earliest surviving school of solo koto music is Tsukushi-goto. It was first noted on the island of Kyushu in the late 16th century where, over the centuries, court refugees and exiles gathered during upheavals in Kyōto. Earlier Chinese influences also are claimed as part of its creation, though historical facts are obscure. Tsukushi-goto repertoire is said to begin with variants of *imayō* court songs. Sets of songs were accompanied by the koto and sometimes by the three-stringed plucked samisen (*shamisen* in Tokyo dialect). The sets were called *kumiuta,* a term applied to much of the chamber music that followed. The 16th-century priest Kenjun is credited with the creation of the school and its first compositions. The tradition became more secular when it appeared in Edo. There, a 17th-century blind musician named Johide, claimed as a student of Hosui, a student of Kenjun, developed his own version of such music. He added compositions in more popular idioms and scales, named himself Yatsuhashi Kengyō, and founded the Yatsuhashi school of koto. The title Yatsuhashi was adopted later by another apparently unrelated school to the far south in the Ryukyu Islands.

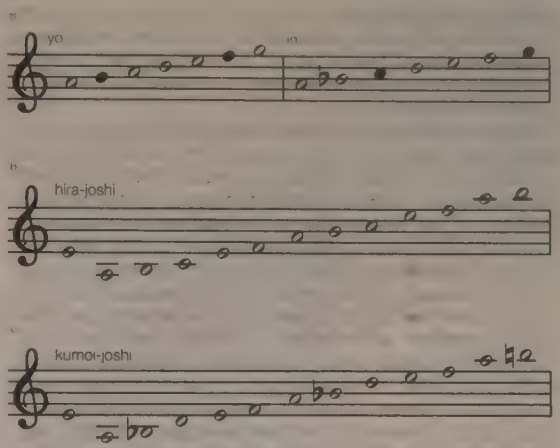
Additional schools of popular, or "vulgar," koto (*zokuso*) reflected the mercantile life of the new Tokugawa (also called Edo) period (1603–1867). In 1695 another third-generation extension of the Kenjun's koto tradition was Ikuta Kengyō, who began his Ikuta school. The term *kengyō* had been one of the basic ranks of musicians under the guild system and so is frequently found in professional names, but the name Ikuta remained as one of the primary sources of koto music until the creation of still another school by Yamada Kengyō (1757–1817). In present-day Japan the Ikuta and Yamada schools remain popular, whereas the earlier traditions have faded considerably. Both schools have provided famous composers; and there are several pieces from their schools, as well as a few earlier works, that are now shared by the guilds as part of the classical repertoire of the koto. The slightly longer and narrower shape of the Ikuta koto produces a tone easily distinguishable from that of the Yamada school.

Koto music is known in general as *sōkyoku.* In the koto solo instrumental music (*shirabemono*), the most important type is the *danmono,* a variation piece in several sections (*dan*), each normally of 104-beat length. The term for koto chamber music, *sankyoku,* means music for three. The standard instrumentation today consists of a koto player who also sings, along with performers on a three-stringed plucked samisen lute and an end-blown *shakuhachi* flute. In earlier times a bowed variant of the samisen called the *kokyū* was used more often than the flute. The basic genre of chamber music is called *jiuta* and combines the earlier *kumiuta* tradition of accompanied song with instrumental music by alternating sections with singing (*uta*) and instrumental interludes (*tegoto*). After the 19th century a second embellishing koto part (*danawase*) often was added to the instrumental interludes. Innovations carried out during the 20th century will be covered later in this article.

Tunings and notation. Each school of koto music from the courtly tradition to the present time involves changes in the structure of the instruments as well as changes in playing method and notation. The ancient court koto (*gaku-so*) is similar to the modern koto and is played with picks (*tsume*) on the thumb and first two fingers of the right hand or with bare fingers, although, unlike the Ikuta and Yamada styles, the left hand is not used to alter the tone by pressing the string on the other side of the movable bridges. Its notation consists primarily of the names of basic patterns in addition to occasional melodic fragments and the text. The survival of such music is dependent on a continuing viable rote tradition; thus, most of the tradition is lost.

The tunings of the 13 strings of the court koto were derived from the modes of the *ryo* and *ritsu* scales of the earlier periods. The tunings used in the Edo koto traditions, however, reveal new, apparently indigenous, tonal systems. These concepts were eventually categorized under the two scales called *yo* and *in,* shown in notation XIII-A. The tunings in XIII-B and XIII-C reflect the new kinds of pentatonism of the period with their use of half steps.

XIII



The *hira-joshi* tuning appears in such famous early works as *Rokudan* (*Six Dans*) ascribed to Yatsuhashi Kengyō, the "founder" of the modern koto styles. In all, there are some 13 standard tunings for the koto and many variants. Like all the other popular music in Japan from the 17th century on, these koto tunings are based either on the older tradition preserved in part in the *yo* form or on the more "modern" *in* scale. One can note in the 19th century occasional pieces deliberately written in the previous gagaku mode style as well as the use of the Holland tuning (*oranda-choshi*), the Western major scale derived from the Dutch business area on Deshima in Nagasaki. Nevertheless, the *yo-in* system remains the fundamental tonal source for new Japanese music from the 17th century on, exceptions being revived court music, new nō plays, and the work of avant-garde composers after World War II.

Printed collections

The earliest printed notations of koto, samisen, and flute pieces from the Tokugawa period are found in the *Shichiku shōshinshū* (1664), the *Shichiku taizen* (1685), and the *Matsu no ha* (1703). Although many sections of such collections contain only the texts of songs, one can find certain pieces that parallel the line of words with numbers representing strings on the koto or finger positions on the samisen, names of stereotyped koto patterns, or mnemonics for the particular instrument with which the piece is learned. In the late 18th century both the koto and the samisen traditions developed more visually accurate notations. The koto version (first seen in the *Sōkyoku taisho,* 1779) used various-size dots to indicate rhythm. In the early 19th century, string numbers were placed in columns of squares representing rhythm, as in the system mentioned earlier in Korea. The numbers and squares eventually were combined with the $\frac{2}{4}$ bar-line concept of the West; so that the notations of both schools today, although separate systems, maintain a balance of traditional and Western ideas. Their modern compositions attempt to do the same as well; but before they can be treated, attention must be given to the traditions connected with the other major instruments of the Tokugawa period.

Schools of shakuhachi flute music. The *shakuhachi* end-blown flute is a variant of the Chinese *hsiao,* and examples of it can be found in the famous 8th-century Shōsō-in treasure house mentioned earlier. During the Muromachi period (1338–1573) a smaller Japanese version called the *hitoyogiri* became popular as a solo instrument, but the best-known form of the *shakuhachi* is the one developed in the Tokugawa period. The instrument was used by *komusō,* priests who begged or sometimes spied while wandering through the streets playing the flute incognito, their heads covered by a special wicker

basket hat. With the changes in contemporary Japanese society, many former warriors no longer carried their swords, whereas young merchants carried more money. One curious side effect of such changes was the occasional appearance of a *shakuhachi* tucked in the back of one's belt for use as a musical device or as a club.

The major schools of *shakuhachi* music today come from guilds, the Meian and Kinko, whose origins derive from two sects of an earlier Fukeshu guild of *komusō* priests. In the Meiji era (1868–1912) the monopoly rights of the various music guilds of the previous period were abolished; and a Tozan school was founded for teaching the music to amateur musicians, a custom soon adopted by the other guilds.

The instruments of all schools may vary in size and the number of finger holes for the purpose of pitch as well as differences in timbre ideals. The standard *shakuhachi* has four finger holes along the front and one thumb hole behind. A bell is formed by the bamboo root stems at the end of the flute. The mouthpiece is cut obliquely outward, and a small piece of bone or ivory is inserted at the blowing edge in order to help produce the great subtle variety of tones typical of *shakuhachi* music. The basic repertoires of the music are divided into three general types. Original pieces (*honkyoku*) are those claimed to be composed by the founders or early teachers of a given school, whereas outside pieces (*gaikyoku*) are taken from other genres or other schools of *shakuhachi* music. New pieces (*shinkyoku*) continually appear and are kept in that category. *Shakuhachi* notation varies with each school; however, all are based on mnemonics with which the music is taught. Given the exceptional subtlety of tone changes and ornamentation in all traditional *shakuhachi* music, such a notation system seems quite logical. The beautiful introverted sounds of *shakuhachi* music seem closer to Buddhist chant than to other instrumental forms and are best learned by the ear and heart rather than by the eye and brain.

Samisen music. The three-stringed plucked lute of Japan is known as the *shamisen* in the Tokyo area or as the *samisen* in the Kansai district around Kyōto. It seems to have arrived in Japan as an import of the *sanshin*, or *jamisen*, from the Ryukyu Islands in the mid-16th century. The Ryukyu form of the instrument, with its oval body and snakeskin, is obviously derived in turn from the Chinese *san-hsien*. Such an origin is reinforced by collections of early Ryukyu music, which use a so-called *kukunshi* notation similar to the Chinese symbols shown in notation V. The Japanese samisen underwent considerable physical change, its body being rectangular and the skins coming from a cat or dog. Apparently under the influence of contemporary *biwa* lute traditions, the plectrum of the instrument was changed from the talonlike pick of the Ryukyus to a wooden or ivory *bachi* with a thin striking edge. In addition, the lowest string was kept off the small metal upper bridge near the pegbox so that it produced a buzzing sound (*sawari*) distinctly reminiscent of the tone of a *biwa*. The three basic tunings of the Japanese instrument are *hon-chōshi* (b–e′–b′; b represents the B below middle C, b′ the B above); *ni agari* (b–f♯′–b′); and *san sagari* (b–e′–a′). These tunings have remained standard to the present day, although there are occasional variants.

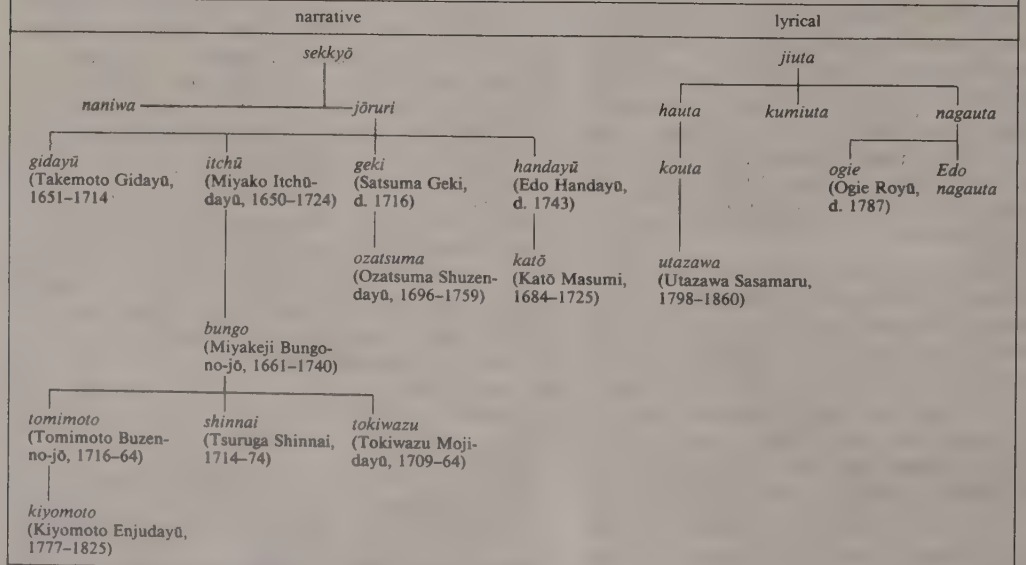
Greater variety is found in the many genres of samisen music. The earliest types seem to have been played by old *biwa* entertainers around Ōsaka, a city then called Naniwa; hence the name of the new genre was *naniwa-bushi*. Samisen was used for folk music and party songs, but, in keeping with the *biwa* origin of the first performers, narrative music was of prime importance. Such music became known as *jōruri*, the term being derived from the title of a famous story of the princess Lapis Lazuli (*Jōruri-hime monogatari*). As different guilds of samisen evolved, it was possible in modern times to divide them into two basic styles: narrative traditions (*katarimono*) and basically lyrical musics (*utaimono*). Table 2 is an outline of the development of these two styles in terms of genre names. *Sekkyō* was an earlier form of Buddhist ballad drama for the general populace and thus is placed at the beginning of the narrative style, for *sekkyō-bushi* was eventually done with samisen accompaniment. The term *jiuta* has already been mentioned as one of the early chamber music forms and thus starts the lyrical list.

Jōruri, or narrative, music

Turning to the narrative list first, one finds a mass of names, most of which after *naniwa* and *jōruri* are derived from the professional name of the musician who began the style. Except for the terms *ogie* and *utazawa*, the names for the lyrical styles are more descriptive. It has already been noted that *kumiuta* means a set of songs. The terms *hauta* and *kouta* stand for short lyrical pieces such as would be heard in a teahouse or at a banquet. *Nagauta* means a long song and represents the major genre in this category, which will be described presently. Each of the styles listed in Table 2 uses a samisen of different size with different weight bridges and design of plectrums. The voice quality of the singers is quite different as well. For example, a professional *shinnai* singer would find the performance of *gidayū* as difficult as would a French opera specialist attempting to sing Wagner.

The most famous and perhaps most demanding of the

Table 2: Genres of Samisen Music*



*Names of founders of some styles are given in parentheses.

narrative styles is *gidayū*, named after Takemoto Gidayū (1651–1714), who worked with Chikamatsu Monzaemon in the founding of the most popular puppet-theatre tradition (known as bunraku) of Ōsaka. The *gidayū* samisen and its plectrum are the largest of the samisen family, and the singer-narrator is required to speak all the roles of the play, as well as to sing all the meditations and commentaries on the action. The part is so melodramatic and vocally taxing that the performers are often changed halfway through a scene. There is little notated in the books (*maruhon*) of the tradition except the words and the names of certain appropriate stereotyped samisen responses. The samisen player must know the entire drama by heart in order to respond correctly to the interpretations of the text by the singer. The two musicians sit on a platform to the stage left of the theatre and through the intensity and skill of their performance help bring life and pathos into the wooden characters who move with frighteningly realistic gestures in the hands of three puppeteers. The power of *gidayū* is such that it can be heard in concert versions as well. In the 19th century a school of female performers (*onna-jōruri*) carried on the concert tradition with equal ability.

Music for the puppet theatre

Kabuki theatre. The *nagauta* form of lyric music, like most of the other narrative forms, began with a close relation to the kabuki popular theatre of the Tokugawa period. The first kabuki performances used instruments (*hayashi*) from the nō drama. Because kabuki was related to the flourishing demimonde of the major cities, however, the music of the party houses and brothels was soon added to the theatre. By the mid-17th century the names of *nagauta* singers and samisen players were listed on posters along with the cast. In the same manner, the names of musicians in many of the other genres listed in Table 2 were adopted to denote parts of a play. Although nearly all the music listed can be heard in concert forms today, the major genres still included in kabuki productions are *gidayū*, *tokiwazu*, and *kiyomoto* from the narrative styles, and *nagauta* from the lyrical. Rather than being discussed individually, they will be viewed in the total theatrical context and later brief reference will be made to their concert forms.

Onstage music. Kabuki as theatre is discussed below in the section *Dance and theatre: The development of dance and theatre in the East Asian nations.* Its musical events can be divided into onstage activities (*debayashi*) and offstage groups (*geza*). In plays derived from puppet dramas, the *gidayū* musicians, called here the *chobo*, are placed on their traditional platform offstage left or behind a curtained alcove above the stage-left exit. If other genres are used, the performers are placed about the stage according to the scenery needs of the play. There are some plays in which several different kinds of onstage music are required, a situation called *kake-ai*. The most common dance scene today, however, is one in which the onstage group consists of *nagauta* musicians and the nō *hayashi*. The samisen and singers are placed on a riser at the back of the stage, and the *hayashi* sit before them on floor level—thus, their other name of the *shitakata*, meaning "the ones below."

There are as many different types of dances that require different kinds of music as there are in Chinese or Western opera. In a general view, perhaps the most intriguing side of this variety is the relation of the older drum and flute parts to the vocal and samisen melodies of the Tokugawa period. In totally kabuki-style pieces, the *tsuzumi* drums play a style called *chirikara* after the mnemonics with which the part is learned. The patterns of this style follow closely the rhythm of the samisen part. If the nō flute is used as well, it is restricted to cadence signals; if a simple bamboo flute (*takebue* or *shinobue*) is substituted, it plays an ornamented (*ashirai*) version of the tune. There are many sections, however, in which the drum patterns and nō flute melodies discussed earlier are combined with samisen melodies. In a classical repertoire of hundreds of set pieces, there are many different combinations, but to many listeners these situations seem rather puzzling at first hearing, with apparently two kinds of music going on at the same time. If the situation is from a play derived from a former nō drama and uses the full *hayashi*, one notes first that the flute is not in the same tonality as the samisen nor is it playing the same tune. The drums in turn do not seem to relate rhythmically to the melody, as they do in the *chirikara* style. The drums and flute are, in fact, playing named stereotyped patterns normally of eight-beat length as in the nō. The essential difference between them and the samisen melody is that they do not seem aurally to have the same first beat. A given samisen melody will often make room through silence for an important vocal call in the drum patterns, but the deliberate lack of coordination of beat "one" creates a vital rhythmic tension that makes the music drive forward until it is resolved at a common cadence. Each part is internally rigid and progressive, but its conflict with the other parts forces the music (and the listener) to move the musical event through a time continuum toward a mutual completion.

Tension between simultaneous styles

The nō flute music is frequently related to the *taiko* stick-drum rhythm, so that they can be considered as a common unit rather than separate parts. There are situations in which the *tsuzumi* play *chirikara* patterns in support of the samisen melody, while the *taiko* and nō flute play either nō patterns or later kabuki-named drum patterns "out of synchronization" with the other music. At such moments one can see that in kabuki dance music, as in Western Classical music, there are three kinds of musical needs. In the West they are melody, rhythm, and harmony. In this music they are melody, rhythm, and a third unit of one drum and a flute that functions like harmony although its sound is totally different. If this third Japanese feature is called the dynamism unit, then it can be said that *nagauta* dynamism and Western traditional harmony both serve to colour the line, to create tension that drives the music onward, and to help standardize the formal design of the piece by clarifying cadences or by creating the need for them. All this brings back the earlier point that music is not an international language. The equally logical but different aspect of this music is certainly most obvious and striking.

The formal aspects of kabuki music are as varied as the plays with which music is connected. In dance pieces derived from nō plays, many of the sectional terms of the nō mentioned above are found. The classical kabuki dance form itself often consists of sections divided into the traditional tripartite arrangement as shown below:

deha or *jo*
oki michiyuki

chūha or *ha*
kudoki, monogatari, odori ji

iriha or *kyū*
chirashi, dangire.

Generally speaking, the *oki* represents all kinds of introductory instrumental sections (*aigata*, or in this case *maebiki*) or vocal parts (*maeuta*) before the entrance of the dancer. The *michiyuki* usually incorporates the percussion section as the dancer enters. The term *kudoki* is found in the early history of samisen music as a form of romantic music and is used here for the most lyrical section, in which the percussion is seldom heard. The *monogatari* (story) relates to the specific plot of the dance, and the *odori ji* is the main dance section, rather like the *kuse* or *mai* of the previous nō form. During this section, the bamboo flute may appear for contrast and, in nō style, the *taiko* drum may be important. The *chirashi* contains more active music, and the final cadence occurs during the *dangire*. There are endless variations and extensions of this form, but the many specific instrumentational and stylistic traits found in each of these sections help the listener to become aware of the logical and necessary progression of a given piece through a moment of time to its proper ending.

Changes in notation in the 18th century

Most early collections (*shōhon*) of onstage music consisted of the text and samisen mnemonics (*kuchi-jamisen*, mouth samisen) of instrumental interludes (*ai-no-te*). In the 18th century some of the lyrical forms began to use syllables to represent fingering positions on the instrument, a system called the *iroha-fu*. In 1762 a set of circles

with various extra markings along with the string number were combined in a book called the *Ongyoku chikaragusa* to create a more accurate if complicated system. Further rhythmic refinements were created in the 1828 *Genkyoku taishinsho,* but it was not until the modern period that Arabic numbers in the French *chevé* style (apparently learned in Germany by Tanaka Shōhei) were combined with Western rhythmic and measured devices to create notations that could be sight-read without the aid of a teacher. Three variations on this technique form the basis of most modern samisen notations, although occasional pieces can be found in Western notation as well. Thus, it is possible to purchase large repertoires of *nagauta, kouta,* or *kiyomoto* music for performance or study alone. Motivating such notational changes was the increased interest during the mid-19th century in samisen music composed for concert performance (*ozashiki*) rather than as dance accompaniment. Such a tradition is common practice for all the samisen genres today.

Offstage music. Returning to the theatre, one finds rather different music offstage. This *geza,* or *kagebayashi* (shadow *hayashi*), music is normally placed in a small room on stage right with a view of the drama through a bamboo curtain. The music consists of special samisen and vocal pieces and a great variety of percussion signals. For example, a huge *ō-daiko* barrel drum with two tacked heads signals the beginning of a program, in keeping with the sounds given by the same drum from a tower over the entrance of very early kabuki theatres. Other drums, bells, gongs, and clappers are used to reinforce stage action, and special offstage songs may set the mood or location of a scene, particularly in those scenes in which onstage musicians do not appear. For example, the singing of the offstage song "Eight Miles to Hakone" will tell an audience that the scene is set along the old Tōkaidō (the ancient road between Tokyo and Kyōto), whereas the sound of waves (*nami-no-oto*) beat on the *ō-daiko* drum indicates that the scene is on the road near the sea. A type of offstage song called *meriyasu* may be used to reflect the silent thoughts of the stage character, while the call and response of occasional beats offstage of two *ko-tsuzumi* drums will place a scene in a mountain area with its echoes. As in Western musical theatre and films, many of the sounds are naturalistic, whereas others are traditional means of evoking desired responses from an audience.

Music and dramatic content

Theatregoers in both traditions are often unaware consciously of the means used for such reactions even though familiarity has made their dramatic value very real indeed. The specific musical devices used in a given kabuki play are under the control of a headman, *hayashi gashira,* who works with the first samisenist, the actors, and the director to produce the desired results. Thus, the musical contents of a given play may change with different productions. In kabuki the combination of offstage and onstage music creates a total atmosphere that has few parallels in other world theatres. Perhaps it comes as close as anything to the composer Richard Wagner's ideal of the all-embracing art form (*Gesamtkunstwerk*).

Biwa, vocal, and folk music. During the late 19th century the *biwa*-accompanied narratives enjoyed a revival. The blind-priest *biwa* (*moso biwa*) tradition had originally been divided into two schools named after the provinces in Kyushu from which they came, Chikuzen and Satsuma. The tradition declined greatly over the years. When the Imperial restoration began in the Meiji period, many members of the new administration were from those provinces. Thus new schools of narrative *biwa* music arose under those two names, influenced at this time by several samisen narrative traditions. The topics of the new *biwa* pieces were often military and appropriate to the modernization period. The 19th century also was one of Japan's periodic revivals of interest in things Chinese, reduced somewhat with the advent of the Sino-Japanese War of 1894–95. Another late Tokugawa period style was *shigin,* the singing of Chinese poems in an intense solo style quite unrelated to the Heian *rōei* tradition of Chinese-based songs. *Shigin* was later accompanied by *shakuhachi,* and during the increased military spirit of the Meiji period it was combined with a posturing sword dance, *tsurugi-mai.* It also appeared in *biwa* concerts and could still be heard on rare occasions after World War II.

Courtly writings have left little information about the music of the peasants in any detail, but some folk songs and theatricals of the Tokugawa period remain for modern study. The rice-planting, harvesting, and other work songs that survive may retain ancient melodies and may also be evidence of the indigenous origins of the *yo-in* scale systems to which most such music belongs. In this context, the first phrase of the folk song "Kuroda-bushi" is shown in notation X-D as it is said to have been derived originally from a Heian period *imayō* based on the gagaku piece shown in X-A. Most folk songs are, of course, regionally functional but historically vague and subject to the normal changes of any oral tradition. Viewing as a whole both the performance practice and voice qualities of Japanese folk music, one finds a great variety of styles. Such richness may reflect the long periods of Japanese feudalism, which fostered many different musical dialects.

Work songs, theatricals, and festivals

The many processionals and pantomimes of folk theatricals are accompanied by flutes and percussion, the generic term for such ensembles being *hayashi.* During the Tokugawa period the Shintō shrines of Edo (Tokyo) developed festival ensembles (*matsuri bayashi*) for the various major districts of the city. Most of these combine a bamboo flute with two folk-style *taiko* stick drums, an *ō-daiko* barrel drum, and a small hand gong called the *kane,* or *atarigane.* When such groups are playing general festival music, they all use a suite of five pieces: *yatai, shoden, kamakura, shichome,* and another *yatai.* However, their versions of each piece can be very different. When dance or pantomime is involved, the *sato-kagura* music mentioned earlier is used. The *kagura-bue* flute is often replaced by the nō flute. It combines with an *ō-daiko* and a *diabyoshi* barrel drum. The patterns on the heads of the latter contain East Asian male-female designs. One head is struck with thin bamboo sticks, the drum sitting to the side so that the player can better see the dancer. Lion dance (*shishi mai*) ensembles often use a trio consisting of a bamboo flutist, a gong player, and a drummer who plays a *taiko* and a small *odeko* barrel drum. Cymbals (*chappa*) and samisen may appear in other folk pantomimes or dances. The most common folk dances are the summer *bon odori,* traditionally performed in circles around a high platform (*yagura*) where the musicians or tape machines are located.

Given the oral base of all folk music, many songs are lost with the demise of another old farmer or worker. Scholarly and commercial interest in national music remains strong, however. Folk song preservation societies (*minyo hozon kai*) exist whose functions are to preserve "correct" performances of a single folk song. Such specificity seems unique to Japan. Regional and international folk-based Japanese ensembles flourish, and the summer dances can be seen in Japanese communities from Tokyo to Detroit.

Preservation of folk music

THE MEIJI PERIOD AND SUBSEQUENT MUSIC

Sources of Western influence. The period of Japanese history after 1868 is often thought of primarily in terms of its Westernization. The three major sources of Western music in Japan were the church, the schools, and the military.

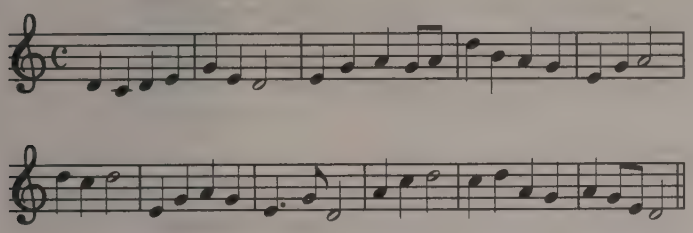
Religious and military music. Christian music had, in fact, been introduced into Japan as early as the mid-16th century with the arrival of Portuguese merchants and Roman Catholic priests. With this importation came Catholic music and Western musical instruments, the most lasting of which was the double-reed shawm, which survives today as the tuneful accessory of itinerant noodle sellers. The bowed *rebeca* lute may have combined with the Chinese *hu-ch'in* in the creation of the bowed *kokyū* of 17th-century Japan. However, the suppression of Christianity in that century destroyed the bamboo organs, choirs of mass singers, and most of the other direct Western musical imitations until the Meiji restoration. The official doctrine of new religious freedom in 1872 brought large numbers of Protestant missionaries into action, and collections of hymns with Japanese text were printed by 1878. Interdenominational editions were necessary by the 1890s. Since that time, standard Catholic and Protestant musical

activities can be found and, with the international growth of Tokyo, one can even add the sounds of synagogues and a mosque. But the growth of musical acculturation in Meiji Japan is better seen in its other foreign imports.

Band music, as part of a military table of organization, had already been tried in Dutch style at a military school in Nagasaki during the early 19th century. After Matthew C. Perry's arrival in 1853, every foreign delegation to Japan did its best to impress the natives with marching bands (Perry added a minstrel show). Thus, the various Japanese regional and national military leaders were quick to add such organizations to their modernized armies. The emperor was equally aware of the Western musical values displayed by the first foreign missions and ordered that the gagaku musicians be trained in band music as well. A navy band from the Satsuma clan gave the first Japanese public performance of this new music at the opening of the railroad in 1872, and in 1876 gagaku musicians made their debut as band musicians on the occasion of the emperor's birthday. The training of the many new ensembles was in the hands of English, French, and German bandmasters, and new music was created by them or by their Japanese students to match the spirit of Meiji modernism. The most famous case is the national anthem, "Kimi ga yo," which was one of the few successful early attempts at combining Western and Japanese traditions. A British bandmaster, William Fenton, teaching the Japanese navy band, worked together with gagaku musicians through several unsuccessful versions; and the search continued through his German successor, Franz Eckert. A court musician, Hayashi Hiromori (1831–96), is credited with the melody shown in notation XIV, which was given its premiere in 1880 and has remained the national anthem since that time. Hayashi first wrote it in traditional gagaku notation; and Eckert "corrected" it with Western harmonization, noting that it fit in both a gagaku mode (*ichikotsu*) and one from the Western church tradition (Dorian). As Japan's military prowess grew, standard Western-style marches and patriotic pieces dominated the repertoire. They also influenced popular music with such genres as *rappa-bushi* (literally, "bugle songs") as well as music in the schools.

Collaboration of Western and traditional Japanese musicians

XIV



Music education. Public-school music in Japan was organized by a member of a Meiji educational search team, Izawa Shūji (1851–1917), and a Boston music teacher, Luther Whiting Mason (1828–96). Mason was brought to Japan in 1880 to help form a music curriculum for public schools and start a teacher-training program. Although there was much talk of combining the best of East and West, the results of the sincere efforts of an American late-Victorian and a Japanese bureaucrat were less than glorious. The first children's songbook, the *Shōgaku shōkashū* (1881), contained either Western pieces with Japanese words or songs newly composed by Mason.

The primary sources of Western tunes were those pieces from Boston schoolbooks that appeared to be pentatonic. Through this method songs like "The Bluebells of Scotland" spoke of beauty ("Utsukushiki"), "Auld Lang Syne" concerned fireflies, and Stephen Foster became the major composer of songs known to educated Japanese children. The newly composed songs with their artificial tunes and moralistic words quickly faded away and eventually were replaced by more popular children's school songs based on military music (*gunka*) from the Sino- and Russo-Japanese wars. The teacher-training school became the Tokyo School of Music by 1890 and included instruction in koto and, because of the lack of proper violins, the bowed *kokyu*. The music department of the modern Tokyo University of Fine Arts and Music is still located at the spot of the original school in Ueno Park, Tokyo, with a bust of Beethoven beside the entrance. Koto, samisen, nō music, and Japanese music history are now found there, along with extensive offerings in Western music. However, until the late 20th century, music education was totally Western in orientation. Japanese music was presented in middle-school music appreciation courses only some 10 years after the end of World War II. The teaching of Western-style singing and the use of choruses have become fundamental to a proper education in Japan, with the results that youth and workers' choruses of the 20th century are cut off from original Japanese music. It was only with the rise all over the world in the mid-20th century of searches for cultural or ethnic identities that the Western nature of Japanese music education has been bypassed by some youth. Such a move should be quite clear to followers of Euro-American folk- and minority-group music revivals. In Japan, 20th-century activists, right or left, have attracted youth by the use of the public-school choral tradition in new textual contexts. Behind the robust volume of such functional, harmonized tunes lies the equally viable if quieter sounds of older, traditional music.

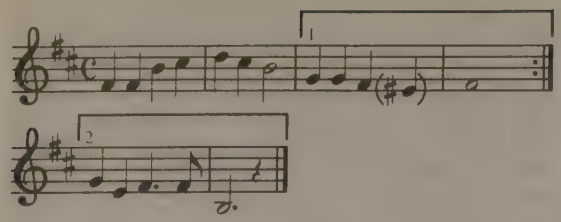
Traditional styles. The pre-Meiji period of 19th-century Japanese traditional music, known generically as *hōgaku* vis-à-vis Western music (*yōgaku*), was generally strong. It has been noted that certain styles of samisen music had been able to create concert repertoires disconnected from dance or party accompaniment. Koto teachers and composers also flourished; and *biwa* music began to return along with court music, paralleling the restoration of Imperial power. The most devastating effect of the restoration was the canceling of monopoly privileges previously held by the various guilds, including those in the music fields. This temporary economic-social setback was overcome by the admission of students from all classes of people and, at the same time, by a concerted effort on the part of more imaginative musicians to make some compromise between their old traditions and the new sounds flowing in from the West. In general, the evaluation of Western music by Japanese traditionalists showed that it differed from *hōgaku* in the following ways: it used other tone systems; it was thicker in texture, with more high and low notes going on at the same time; part of this thickness was sets of chords; it was generally considered better if it were faster and louder and the instruments were played more fancifully; it used more instruments at a time; it used different kinds of metres; and it had other forms, often organized by the concept of first and secondary themes. A survey of late 19th-century and early 20th-century musical experiments in Japan shows that every one of these characteristics was tried out, particularly in koto and samisen music.

Evaluation of Western music by Japanese traditionalists

Perhaps the most obvious and successful composer in the new traditional music (*shin hōgaku*) following World War I was Miyagi Michio (1894–1956), a blind koto teacher in the Ikuta school. In 1921 he composed a piece "Ochiba no odori" ("Dance of the Falling Leaves"), which used two koto, samisen, and a 17-stringed bass koto of his invention. Later works by Miyagi combine orchestras of traditional instruments, sometimes with strikingly successful results, although concerti for koto by some composers, with their mass koto and *shakuhachi* accompaniments, rather negate the entire sound ideal of the original idioms. The 1929 duet for *shakuhachi* and koto, "Haru no umi" ("Spring Sea"), has proven Baroque-like in its performance practice, for it is often heard played by the violin, with koto or piano accompaniment. Its style equals the French composer Claude Debussy in his most "orientale" moments. The Japanese traditionalist's view of Western music described above continued to be employed after World War II with such works as multimovement pieces using mixed orchestras in other contemporary idioms, including electronic manipulations. Such trends are best seen in the context of Western-style Japanese composers.

Composers in Western styles. Although graduates of the Tokyo School of Music and modernized court musicians were involved in many of the first concerts and com-

XV



positions in Western classical music, the major Japanese forces in this direction came from young men who studied in Europe. The most famous surviving composition of this era is *Kojo no tsuki* (*The Ruined Castle*), written in 1901 by Taki Rentarō after his training in Germany. The first line, shown in notation XV, reveals, with its use of E or E♯, a conflict between the Western minor and the Japanese *in* scales. In its piano-accompanied version it recalls the style of Franz Schubert, but as sung in the streets it sounds Japanese. Yamada Kōsaku was training in Germany when the Meiji era ended (1912) and returned to Japan with a new name, Koscak, and a strong interest in the founding of opera companies and symphony orchestras, as well as in the teaching of Western music. His opera, *Kurobune* (1940; *The Black Ships*), deals with the opening of Japan to the West and reflects his knowledge of Wagnerian style. Attempts at nationalistic operas can be represented better by the work *Yuzuru* (1952; *Twilight Crane*) by Ikuma Dan. The plot is a Japanese folktale, and, although the musical style is a mixture of the music of Maurice Ravel and the late works of Giacomo Puccini, one finds as well deliberate uses of folk songs and idioms. Shimizu Osamu is perhaps more successful nationalistically in his choral settings of Japanese and Ainu music, in which the style of vocal production and chordal references seems to be a more honest abstraction of Japanese ideals. Mamiya Michio combined traditional timbres with 12-tone compositional technique in a koto quartet. Mayuzumi Toshirō has produced many clever eclectic results in such works as his *Nirvana Symphony* (1958); Buddhist sutra texts mix with a combination of choral writing in the style of Igor Stravinsky, orchestral tone clusters, and sweeping vocal lines derived from Japanese Buddhist chant style.

It has often been felt that no true combination of Japanese and Western music would be possible until there was some composer who was equally knowledgeable in both Western and Japanese traditional styles. Such a musical, aesthetic barricade seemed unbroken until the last third of the 20th century, when international music styles made culturally transcendental eclecticism a viable medium for those composers with enough talent and insight to control the infinite idioms available to them. In Japan, Takemitsu Toru seems a likely candidate for such an accolade. His music is totally contemporary and never directly "orientale," yet some of his senses of timing, texture, and structure are characteristically Japanese.

20th-century musical internationalism

In modern Japan all styles of music are available, from the traditional to the most avant-garde. Fully professional performances of kabuki music are matched by complete Beethoven symphonic series. Huge choruses singing polemics of every type and mass bands of children bowing violins in the widely imitated method of instruction developed by Shinichi Suzuki compete for audiences with intimate recitals of Heike *biwa* music and hundreds of other events. Research in Japanese traditional music has flourished among native scholars as well as among an increasing number of foreign devotees; and national, private, and academic organizations have been founded for the collection, study, and publication of material dealing with all aspects of Japanese musical life.

From the outline of Japanese musical culture given above, it should be evident that old traditions can still be heard along with the newer ones. For the most part, the older forms probably do not sound the same today as they did in their heyday. Such changes in traditions are inevitable, however, and are common to music in most other world cultures, including the Western. For example, present-day gagaku performances are undoubtedly different from those of 1,000 years ago, but Mozart symphonies as well do not sound the same as they did in the 18th century. Now modern technology has made it possible to "freeze" a given performance of some musical event through a recording. Each musician in each generation may choose as he desires to add fresh flavour to such earlier items or leave them "pure." Part of the charm and fascination of Japanese music is that it still offers so many stylistic listening and studying choices to anyone curious or energetic enough to want to know them better. A major point of this entire discussion is that none of the various styles of East Asian music is any more mystical or incomprehensible than is Bach or Beethoven. Each tradition is simply different. All of them are also logical and—perhaps of greater importance—they are beautiful to those who learn their special forms of musical language. (W.P.M.)

DANCE AND THEATRE

Origin of dance and theatre in religious customs

From ancient times dance and theatre have played a vital role in China, Korea, and Japan. Many performances of plays and dances were closely tied to religious beliefs and customs. In China, records from about 1000 BC describe magnificently costumed male and female shamans who sang and danced to musical accompaniment, drawing the heavenly spirits down to earth through their performance. Impersonation of other characters through makeup and costume was occurring at least by the 4th century BC. Many masked dances in Korea have a religious function. Performances invoking Buddha's protection are especially popular and numerous in Japan and Korea. Throughout East Asia the descendants of magico-religious performances can be seen in a variety of guises. Whether designed to pray for longevity or for a rich harvest or to ward off disease and evil, the rituals of impersonation of supernatural beings through masks and costumes and the repetition of rhythmic music and patterns of movement perform the function of linking man to the spiritual world beyond. Hence, from the earliest times in East Asia, dance, music, and dramatic mimesis have been naturally fused through their religious function.

In East Asia the easy intermingling of dance and theatre, with music as a necessary and inseparable accompanying art, also derives from aesthetic and philosophic principles (see above). In the West, by contrast, concert music, spoken drama, and ballet have evolved as separate performing arts. Confucian philosophy holds that a harmonious condition in society can be produced by the proper actions of man. Throughout China's history, poems were written to be sung; songs were danced. Zeami (1363–1443), the most influential performer and theoretician of nō drama in Japan, described his art as a totality, encompassing mimesis, dance, dialogue, narration, music, staging, and the reactions of the audience as well. Without arbitrary divisions separating the arts, there has developed in East Asia exceptionally complex artistic forms that produce on their audience an impact of extraordinary richness and subtlety.

Current dance and theatre forms

Puppets, masks, highly stylized makeup, and costuming are common adjuncts of both dance and theatre. Dialogue drama (without music) is rare but does exist. The major dance and theatre forms performed today in East Asia can be loosely classed as unmasked dances (folk and art dances in each country), masked dances (Korean masked dances and *bugaku* and folk dances in Japan), masked dance theatre (nō in Japan and *sandae* in Korea), danced processionals (*gyōdō* in Japan), dance opera (Peking and other forms of Chinese opera), puppet theatre (*kkoktukaksi* in Korea and bunraku in Japan), shadow theatre (in China only), dialogue plays with traditional music and dance (kabuki in Japan), dialogue plays with dance (*kyōgen* in

Japan), and modern, realistic dialogue plays introduced from the West into China, Korea, and Japan in the 19th and 20th centuries.

Characteristics of East Asian dance and theatre

COMMON TRADITIONS

As previously noted, China, Korea, and Japan have been historically close for centuries, thus accounting for their numerous common artistic traditions. From pre-Christian times until the 8th and 9th century AD, the great trade routes crossed from the Middle East through Central Asia into China. Hinduism, Buddhism, some knowledge of ancient Greek, and much knowledge of Indian arts entered into China, and thence in time into Korea and Japan. Perhaps before Christ, the Central Asian art of manipulating hand puppets was carried to China. For more than 700 years, until 668, in the kingdom of Koguryŏ, embracing northern Korea and Manchuria, court music and dances from Central Asia, from Han China, from Manchuria, and from Korea, called *chisŏ* and *kajisŏ*, were performed. Many of the dances were masked; all were stately as befit serious court art. They were taken to the Japanese court in Nara about the 7th century. Called *bugaku* in Japan, they have been preserved for 12 centuries and can still be seen performed at the Imperial Palace in Tokyo, though they have long since died out in China and Korea. In Koguryŏ's neighbouring kingdom of Paekche, a form of Buddhist masked dance play was performed at court, and, in the 7th century, it too was taken to the Japanese court at Nara by a Korean performer, Mimaji, who had learned the dances while staying at the southern Chinese court of Wu-hou. Called *kiak* in Korea and *gigaku* in Japan, the Aryan features of some of its masks clearly indicate Indian (or Central Asian) influence. Such complicated genealogies are common in East Asian performing arts.

Very likely by the 7th century, gypsylike puppeteers, who originally had been nomads from Central Asia and had taken up abode in northern Korea, migrated to Japan. (There may have been a native puppet tradition in Japan as well.) In time the art of puppet manipulation joined with that of epic storytelling to produce the famous bunraku puppet theatre. Musical accompaniment for bunraku and for other popular plays in Japan, such as kabuki, was provided primarily by the samisen, a three-stringed lute, borrowed from China by way of Okinawa. The lion dance, originally from China, is performed in a score of versions in Korea and Japan as well as in China, India, Sri Lanka, and Bali. Certain myths are dramatized in common as well. The story of the angel or nymph who flies down to earth and arouses the love of a mortal man is known in many parts of the world. It is dramatized in Southeast Asia (especially in Myanmar [Burma] and Thailand, as the play *Manora*), in Chinese opera, and in both nō and kabuki theatre in Japan (as *Hagoromo* [*The Feather Robe*]). The legend of the one-horned wizard who traps the dragon gods of rain and causes a searing drought originated in India and was later transmitted by the Chinese to Japan, where it is dramatized in nō (*Ikkaku sennin* ["The One-Horned Wizard"]) and in kabuki (*Narukami* [*Saint Narukami and the God Fudō*]).

Western influences

The direction of artistic exchange was reversed in the 19th century. As part of Japanese national policy following the Meiji Restoration (1868), artists studied Western performing arts. In the early decades of the 20th century, Chinese and Korean actors, dancers, and playwrights studying in Japan took back to their countries Western theory and practice in ballet, modern dance, and theatre. Most influential was the Western dramatic theory of realism. It diametrically opposed the traditional intermingling of music and dance with drama, and it eschewed the stylization and symbolism that lay at the heart of East Asian performing arts for more than 2,000 years. A conflict between traditional and Western performing arts came into being that continues to the present.

As has been noted, dance and theatre are accompanied by music in all except the most unusual cases. The music is especially composed for each bunraku puppet play in Japan and for most dance plays and court dances. Fixed melodies accompany most folk performances. In Chinese opera and in Japanese kabuki, melodies appropriate to scene, action, character, or mood being portrayed are selected from a standard musical repertoire of several hundred tunes. The knowledgeable spectator easily identifies scenes by the music that accompanies them (a similar system is found in Southeast Asian theatre). The close linking of music with dance and theatre can be seen in the Korean drum dance, in which the dancer also is a musician who plays the drum, and in a number of Japanese kabuki and puppet plays that show characters expressing hidden feelings by playing a musical instrument. Equally important, the performer demonstrates to the audience his skill in yet another refined accomplishment.

The performing arts of India are closely linked to sculpture and painting by the unusual phenomenon that bodily positions in all these arts are regulated by similar, indeed almost identical, codes. The code of hand gestures, for example, for the dancer and the actor set forth in the *Nāṭyaśāstra* ("Treatise on the Dramatic Arts"; dated variously from the 2nd century BC to the 4th century AD and later), a treatise on dramaturgy, is identical with that for Buddhist temple sculpture, or painting. Although these hand positions (*mudrā*) from India also are seen in Chinese, Korean, and Japanese statues of the Buddha, they have never been adopted by performing artists (as, by way of contrast, they were by dancers and actors in Cambodia, Thailand, Myanmar, Java, and Bali).

Aesthetic parallels of visual arts and performing arts

In three notable instances, however, the performing arts in China and in Japan can be seen to be closely related to the visual arts. During the Sung dynasty (960–1279) in China, Northern and Southern schools of painting evolved that were totally different in style; the former used bold outline and brilliantly contrasting colours of deep green, blue, and gold, while the latter emphasized delicate, monochrome ink painting of misty landscapes. Northern and Southern schools of opera at the time reflected the same contrasting characteristics: the former dynamic, vigorous, and filled with action, the latter emphasizing wistful emotions and soft, gentle singing. Zen Buddhism was a common source of inspiration in the 15th and 16th centuries in Japan for nō dance drama, for the tea ceremony, for ink painting, and for the art of rock-and-sand gardens. Spareness of form, discipline, and suggestion rather than explicit statement are Zen attributes found in these and other arts cultivated by the military ruling class (samurai) of the time. In 18th-century Japan, a lively and faddish urban culture produced both ukiyo-e woodblock prints and kabuki. In fact, ukiyo-e artists, such as Tōshūsai Sharaku, established their fame by portraying famous kabuki actors as their subjects. Eroticism, verve, brilliant colouring, and an intense interest in the passing moment characterize equally both kabuki theatre and ukiyo-e visual art.

The performing arts traditionally are seen as distinct from literature in East Asia. A century and a half passed in kabuki before the first complete play script was preserved, and in China, where a tradition of written literature goes back to 1400 BC, no play text was considered worth committing to paper until the late Sung, about the 13th century. With few exceptions, playwrights have rarely been accorded the same status as writers of poetry, novels, or criticism. As a result, the performing arts in East Asia succeeded by and large in escaping the stultifying grip that literature came to hold on Indian Sanskrit drama and, some would say, still holds on drama in the West.

Local traditions in East Asian countries

The general outlines of artistic borrowings among East Asian countries can be traced from historical records. But borrowing tells only half of the story. No matter how strong the initial outside influence, in time, assimilation of the foreign art took place. Older native performing traditions reasserted themselves, and new creativity altered the borrowed elements. This can be seen even in *bugaku* dances in Japan; although they are believed to preserve ancient Chinese and Korean forms to a very remarkable extent, native Japanese qualities are also present. Local styles predominate even more in the popular arts. Japanese bunraku puppet plays and kabuki theatre show almost no observable signs of foreign influence. In spite of certain

general cultural similarities, then, the dance and theatre of China, Korea, or Japan exhibit definite local characteristics not shared by the arts of their neighbouring countries.

In China singing became highly developed, and the most important theatre performances are built around song (hence the term Chinese opera). The shadow theatre, known from Morocco through Egypt and Greece and in India, Indonesia, Malaysia, Thailand, and Cambodia, is found in East Asia only in China. In Korea there are scores of court and folk dances and danced plays, but no sophisticated dramatic forms evolved until the 20th century. Masked dances especially are characteristic of Korea. In Japan complex theatrical forms evolved that include dance drama, epic narrative performed as a puppet play, and dialogue dramas either accompanied or unaccompanied by music.

Aesthetic principles

The aesthetic principles that govern dance and theatre in East Asia are radically different from those of the West. Dancers in the West attempt to be free from the pull of the Earth, trying to leap and soar in the air. Dancers in China, Korea, or Japan stand firmly on the dance floor, often scarcely raising their feet in the air; they move in relatively slow and often geometric patterns. Arm and hand movements are important and varied, while in Western dance the hands are little used. Whether movement is dance or not, it is always stylized. Speech is stylized as well, whether it is dialogue or narration, chanted or sung. The intent may be to portray archetypes, human or mythological, especially in shadow and puppet theatre and in masked dances and plays. There is great emphasis on form, both for its ritual value and because audiences are trained to recognize the beauty implicit in form. The East Asian audience is prepared to respond in quick succession to a sequence of different stimuli—physical characterization, human speech, song, narrative commentary, visual composition, formal movement patterns—over long periods of time, for 8 hours in nō or up to 12 hours in kabuki. This differs from the West, where the spectator expects to be exposed to a clearly focused theatrical image for only two or three hours. The East Asian experience is more diverse, more extended, more conventional than the Western experience in the theatre.

A further important characteristic of dance and theatre in China, Korea, and Japan is that performing arts developed very largely within an oral tradition. By and large the performers themselves created the forms; only gradually did specialists in choreography, musical composition, or writing take their places in performing groups.

SOCIAL CONDITIONS

Social position of the performer

It is notable that, although some dance and theatre forms were highly regarded in China, Korea, and Japan, performers were usually looked down upon. Wandering performers especially were despised in the agrarian societies, where attachment to the land was valued and Confucian teaching, strong throughout East Asia, stressed veneration of one's parents, which included tending their graves and making offerings for their welfare in the spirit world. The place of drama or of dance in these societies depended in part upon their audiences, whether they were court nobles, villagers, or town merchants.

Chinese emperors, Korean kings, and Japanese emperors and military rulers (shoguns) all supported performers at their courts. During the T'ang dynasty, the 8th-century Chinese emperor Hsüan-tsung (also called Ming-huang) established schools in the palace city of Ch'ang-an (Sian) for music, dancing, and acting. The latter school was called the Pear Garden (Li-yüan); ever since, actors in China have been called "children of the pear garden" (*li-yüan tzu-ti*). More than a thousand young people from all ranks of society drew government salaries while studying and performing at lavish state banquets and for official ceremonies. Acting or dancing might be a permanent job (at least until old age made one less attractive) at the Chinese court, but in Korea performers at the court held other positions in the government and were mobilized from around the country only for rehearsal and performance. In Japan, dancers and musicians have been attached to the Imperial household from the 7th century until the present time. First *gigaku* and then *bugaku* dances were official performing arts, while shrine dances (*kagura*) were also partly under Imperial patronage. The military rulers of Japan incorporated into their retinues nō actors and musicians beginning in the 15th century, and, in time, provincial lords also began to follow this practice.

Court patronage

Court support resulted in high artistic levels in all countries. Performers were relieved of financial problems and could devote themselves, often full-time through their entire lives, to their art. Audiences were educated and for the most part discerning. The importance attached to official performances undoubtedly spurred artists to extend themselves to their utmost. In time, however, such forms as Japanese nō and *bugaku* and Chinese *k'un-ch'ü* opera became so rarefied that they could be appreciated only by a small elite group.

At the Chinese and Korean courts, young female dancers were part of the ruler's personal retinue (often his concubines); they were not allowed to mix with men of the court, so that some court arts were performed solely by men and others solely by women. This custom and the consequent artistic practice of male and female impersonation is also found in court theatre of Cambodia and Thailand. In Japan, women seldom performed at court, and the major dance and theatre forms have been the province of male performers. Since it was unusual for rulers or courtiers themselves to take part in performance, the court artist was usually a middle-level civil servant.

Folk and popular theatre and dance

Folk performers, on the other hand, are local villagers who, like the *sandae* masked dancers of Korea or the young women who perform festive *ayakomai* dances in Japan, are amateurs who do not live by their art. The midsummer Bon dance for spirits of the dead or early spring rice-planting dances in many areas of Japan or various auspicious dances held at the New Year in Korea and China were performed only once a year, and hence a high level of artistry was not usually achieved. Because many folk performances were held as part of religiously sanctioned rituals (Korean mask plays ensuring harvest, dances and dance plays of many varieties in Japan dedicated to local Shintō deities), performers achieved considerable status in the local community by their participation in these essential communal rites.

Performers of popular dance and theatre in East Asia live—as do commercial artists everywhere—by their ability to draw audiences who are willing to pay money for a seat in a public theatre. The shadow and puppet performers of China, Peking opera actors and musicians, and kabuki and bunraku puppet performers in Japan are popular artists. Neither a part of village culture nor patronized by the court, they have always been held suspect by their rulers. Popular theatre grew in importance in China and in Japan concurrently with the growth of large urban centres and a moneyed, mercantile economy, in the 17th–19th centuries. Today troupes perform nightly through the year, when it is possible, and consequently, in popular theatre, large repertories of standard plays are created (some 350 in kabuki and more than 200 in Chinese opera). Popular theatre forms in China and Japan are intensely theatrical, though they lack literary qualities which would recommend them to the intelligentsia. Indeed, kabuki in Japan and Peking opera in China have had little official status until the mid-20th century in spite of their immense audience popularity and their obvious excellence as performing arts.

The development of dance and theatre in the East Asian nations

CHINA

Formative period. Singing and dancing were performed at the Chinese court as early as the Chou dynasty (*c.* 1111–255 BC). An anecdote describes a case of realistic acting in 402 BC, when the chief jester of the court impersonated mannerisms of a recently deceased prime minister so faithfully that the emperor was convinced the minister had been restored to life. Drama was not yet developed, but large-scale masques (a short allegorical performance with masked players) in which dancing maidens and young

boys dressed as gods and as various animals were popular. Sword-swallowing, fire-eating, juggling, acrobatics, ropewalking, tumbling, and similar stage tricks had come from the nomads of Central Asia by the 2nd century BC and were called the "hundred entertainments." During the Han dynasty (206 BC–AD 220) palace singers acted out warriors' stories, the forerunners of military plays in later Chinese opera, and by the time of the Three Kingdoms (AD 220–280) clay puppets were used to enact plays. These evolved into glove-and-stick puppets in later years.

T'ang period. The emperor Hsüan-tsung showed interest in the performing arts, stimulating many advances in stage arts during the T'ang dynasty (618–907). More than a thousand pupils were enrolled in music, dance, and acting schools. Spectacular masked court dances and masked Buddhist dance processions were part of court life. Three types of play are recorded as having been popular. *Tai-mien* ("Mask") was about Prince Lan Ling, who covered his gentle face with a horrifying mask to frighten his enemies when he went into battle. Some suggest the colourful painted faces of warriors in today's Chinese opera derive from this play. *T'a-yao niang* ("Stepping and Swaying Woman") was a farcical domestic play in which a sobbing wife bitterly complained about her brutal husband, who then appeared and, singing and dancing, abused his wife even more. The embezzling rascal hero of *Ts'an-chün* ("The Military Counselor") became a stock character in later plays. Thus, by T'ang times, three basic types of drama were known: military play, domestic play, and satire of officialdom; and establishment of role types had begun.

Popular types of plays

Sung period. The variety play (*tsa-chü*) was created by writers and performers in North China during the Northern Sung dynasty (960–1127). None of the scripts has survived, but something of their nature can be deduced from the 280 titles which remain and from court records. A play consisted of three parts: a low-comedy prologue, the main play in one or two scenes (consisting of extended sequences of songs, dancing, and perhaps dialogue), and a musical epilogue. Two, three, or four variety plays would be included in a program along with a sampling from the "hundred entertainments." In the following Southern Sung dynasty (1127–1279), northern writers continued composing plays of this general type. None of the 691 professional scripts of which the titles are known has survived. Concurrently a new form of drama, southern drama (*nan-hsi*), emerged in the area around Hang-chou in southern China. Originally the creation of folk authors, it soon became an appealing and polished dramatic form. A southern drama tells a sustained story in colloquial language; flexible verses (*ch'ü*) were set to popular music, making both music and poetry accessible to the ordinary spectator. Professional playwrights belonging to Hang-chou's writing societies (*shu-hui*) wrote large numbers of southern dramas for local troupes. Of these, 113 titles and 3 play texts remain, preserved in an imperial collection of the 15th century. *Chang Hsieh chuang-yüan* ("Top Graduate Chang Hsieh") is probably the oldest of the three texts. It dramatizes the story of a young student who aspires to success, earns a degree and position, but callously turns his back on the girl who faithfully loves him.

Professional theatre districts became established during the Sung dynasty. Major cities contained several districts (17 or more in Hang-chou), with as many as 50 playhouses in a district. Plays performed by puppets and mechanical dolls were extremely popular.

Shadow theatre

A legend attributes the origin of shadow theatre in China to an incident said to have occurred about 100 BC: a priest, claiming to have brought to life the emperor's deceased wife, cast a woman's shadow on a white screen with a lamp. Others suggest the shadow play dates only from the Sung period. In any case it was widely performed in Sung times in the theatre districts. Puppets were made of translucent leather and coloured with transparent dye so they cast coloured shadows on the screen. Shadow plays are still performed in China. Singers, dancers, actors, acrobats, and other performers were all employed at the professional theatres of the districts. Troupes were as small as possible for economic reasons, containing as few as five or six performers. They would tour the countryside if they had no work in the large cities, thus spreading urban styles of performing arts throughout the vast region of China.

Yüan period. Scholars turned to writing drama in the Yüan period (1206–1368) when they were removed from their positions in the government by China's new Mongol rulers, descendants of Genghis Khan. They developed the earlier northern style of *tsa-chü* into a four-act dramatic form, in which songs (in the same mode in one act) alternated with dialogue. Singing was restricted to a single character in each play. Melodies were those of the Peking region. The beauty of poetic lyrics was highly valued, while plot incidents were of lesser importance. About 200 plays survive, from the thousands of romances, religious plays, histories, and domestic, bandit, and lawsuit plays that were composed. *Hsi-hsiang chi* (*The Romance of the Western Chamber*), by Wang Shih-fu, is a 13th-century adaptation of an epic romance of the 12th century. The student Chang and his beautiful sweetheart Ying Ying are models of the tender and melancholy young lovers who figure prominently in Chinese drama. Loyalty is the theme of the history play *Chao-shih ku-erh* (*The Orphan of Chao*), written in the second half of the 13th century. In it the hero sacrifices his son to save the life of young Chao so that Chao can later avenge the death of his family. *Hui-lan chi* (*The Chalk Circle*), demonstrating the cleverness of a famous judge, Pao, is known in the West, having been adapted (1948) by the German playwright Bertolt Brecht in *The Caucasian Chalk Circle*. The class of bandit dramas are mostly based on the novel *Shui-hu chuan* (*The Water Margin*) and its 108 bandit heroes, who live by their wits doing constant battle against corrupt and avaricious officials. The life of the common man is portrayed with considerable reality in Yüan drama, though within a highly formalized artistic frame. The lasting worth of Yüan plays is attested to by the fact that they have been adapted constantly to new musical styles over the years so that Yüan masterpieces make up a large part of the traditional opera repertory.

Ming period. Plays of the Yüan period were widely popular with the people. When under the native Chinese Ming rulers (1368–1644) Mongol influence was eradicated, drama was, for a time, forbidden. Revived in the south, it increasingly became a literary form for a scholarly elite. A renowned Ming play is *P'i-p'a chi* ("Lute Song"), written in 42 affecting scenes, by the scholar Kao Ming in the 14th century. Its heroine, Chao Wu-niang, sets a perfect example of Confucian filial piety and marital fidelity, car-

ing for her husband's parents until their tragic death and then playing the lute to eke out a living as she patiently searches for her husband.

In the mid-16th century, a musician, Wei Liang-fu, of Su-chou, devoted 10 years to creating a new style of music called *k'un-ch'ü*, based on southern folk and popular melodies. At first it was used in short plays. Liang Ch'en-yü, poet of the 16th century, adapted it to full-length opera in time, and it quickly spread to all parts of China, where it held the stage until the advent of Peking opera, two centuries later. Important *k'un-ch'ü* dramatists were T'ang Hsien-tsu (d. 1616), famed for the delicate sensitivity of his poetry, Shen Ching (d. 1610), who excelled in versification, and the creator of effective theatrical pieces, Li Yü (1611–1685). A large-scale performance of *k'un-ch'ü* for the Ch'ing emperor Ch'ien-lung in 1784 marked its high point in Chinese culture. *K'un-ch'ü* had begun as a genuinely popular opera form; it was welcomed by audiences in Peking in the 1600s, but within decades it had become a theatre of the literati, its poetic forms too esoteric and its music too refined for the common audience. In 1853 Su-chou was captured by the Taiping rebels, and thereafter *k'un-ch'ü* was without a strong base of support and declined rapidly.

Origin of Peking opera

Ch'ing (Manchu) period. *Ching-hsi* or *ching-chü* (Peking opera) came into being over a period of several decades at the end of the 18th century, during the Ch'ing dynasty (1644–1911/12). In the wake of the Taiping Rebellion, *k'un-ch'ü* troupes resident in Peking returned to their homes in the south. Their places in Peking's theatres were quickly taken by opera troupes from the surrounding provinces, especially Anhwei, Hupeh, Kansu, and Shansi. Anhwei opera had been performed on the occasion of the emperor Ch'ien-lung's birthday in 1790. Peking opera was born of an amalgamation of elements from several sources: rhythmic beating of clappers to mark time for movements (from Shansi and Kansu), singing in the two modes of *hsi-p'i* and *erh-huang* (from Anhwei), and increased use of acrobatics in fighting scenes. Undoubtedly, court support for Peking opera from Tz'u-hsi (1835–1908), the Empress Dowager, contributed to its rise, but it was also very widely patronized by local audiences. It became the custom to rehearse in public teahouses, and in time these became regular performances providing troupes with much of their financial support.

Differences between *ching-hsi* and *k'un-ch'ü* drama

Essentially, *ching-hsi* was a continuation of northern-style drama, while *k'un-ch'ü* marked the culmination of southern-style drama. Musically they are very different: the former uses loud clappers and cymbals for scenes of action and the penetrating sound of fiddles accompanies singing; in the latter the flute is the major instrument, and strings and cymbals are absent. A limited number of melodies are repeated many times in Peking opera (set to different lyrics), while in *k'un-ch'ü* the melodic range is much wider. Peking opera lyrics are in colloquial language (they are often criticized as lacking in literary merit). Overall, the newer opera form is highly theatrical and vigorous, while the older form is restrained, gentle, and elegant. Some Peking operas are Yüan plays or *k'un-ch'ü* operas adapted to the new northern musical system. Many plays first staged as Peking opera are dramatizations of the war novel *San-kuo chih yen-i* (*Romance of the Three Kingdoms*), written in the 14th century by Lo Kuan-chung. Mei Lanfang, the most famous performer of *ching-hsi* female roles in the 20th century, introduced a number of these highly active military plays into the repertoire. *K'un-ch'ü* dramas told a long and involved story in great detail, often in 40 or 50 consecutive scenes. It became the custom in Peking opera to perform a bill of a number of acts or scenes from several plays, like a Western concert program.

A *ching-hsi* troupe performing a scene from *Pai-she chuan* (*The White Snake*).

Concurrent with the national forms of drama mentioned before, local opera is found in every area of China (the different forms have been estimated at 300). These operas are performed according to local musical styles and in regional languages. General characteristics of most forms of Chinese opera are similar, however. Action occurs on a stage bare of scenery except for a backdrop and side-pieces. A table and several chairs indicate a throne, wall, mountain, or other location. (More elaborate scenery is used in Canton and Shanghai, influenced by Western drama and motion pictures.) Actors enter through a door right and exit through a door left. Costumes, headgear, and makeup identify standard character types. Actors play a single role type as a rule: male (*sheng*), female (*tan*), painted-face warrior (*ching*), or clown (*ch'ou*). Each role type can be subdivided into several role subtypes. Actors undergo seven years of training as children, during which time their appropriate role type is determined. Singing is essential for *sheng* and *tan* roles; minor actors and actors of clown roles must be skilled in acrobatics that enliven battle scenes. Singing is accompanied by a large number of conventionalized movements and gestures. For example, the long "flowing water" sleeves that are attached to the costumes of dignified characters can be manipulated in 107 movements. Pantomime is highly developed, and several scenes have become famous for being enacted without dialogue: in *Pai-she chuan* (*The White Snake*) a boatman rows his lovely daughter across a swirling river; in *San cha kou* ("Where Three Roads Meet") two men duel in the dark; in *Shi yu chuo* ("Picking Up the Jade Bracelet") a maiden threads an imaginary needle and sews. Symbolism is highly developed. Walking in a circle indicates a journey. Circling the stage while holding a horizontal whip suggests riding a horse. Riding in a carriage is represented by a stage assistant holding flags painted with a wheel design on either side of the actor. Four banners indicate an army. A black flag whisked across the stage means a storm, a light blue one a breeze or the ocean. Chinese opera is one of the most conventionalized forms of theatre in the world. It has been suggested that the poverty of troupes and the need to travel with few properties and little scenery led to the development of many of these conventions.

Role of Confucian morality in drama

Confucian morality underlies traditional Chinese drama. Duty to parents and husband and loyalty to one's master and elder brother or sister were virtues inculcated in play after play. Spiritualism and magic powers, derived from Taoism, are themes of some dramas, but by and large Chinese drama is ethical rather than religious in direction. Plays were intended to uphold virtuous conduct and to point out the dire consequences of evil. The Western tragic view, which holds that man cannot understand or control the unseen forces of the universe, has no place in Chinese drama; the typical play concludes on a note of poetic justice with virtue rewarded and evil punished, thus showing the proper way of human conduct in a social world.

20th century. With the establishment of the Republic of China in 1912, court support for Peking opera by the Manchu dynasty ended. Troupes, however, continued to perform for private patrons and in public at teahouses and in theatres. Following the liberal ideals of the time, attempts were made to write in colloquial language (rather

than in classical Chinese, as previously), and old plays considered undemocratic were dropped from the repertoire. A school for Peking opera acting, modeled on Western pedagogical methods, was established in 1930, actresses being admitted for the first time in three centuries. The basic style of opera remained unchanged, however.

Influence of Western drama

Western spoken drama (*hua-chü*) was first introduced by Chinese students who had studied in Japan and there learned of Western plays. In 1907 a Chinese adaptation of *Uncle Tom's Cabin* was successfully staged in Shanghai by students, marking the beginning of a proliferation of amateur study groups devoted to reading and staging Western plays. Originally aimed at only a small group of Western-educated intelligentsia, spoken drama's appeal was broadened to the middle class by the China Traveling Dramatic Troupe, which toured many cities from its home in Shanghai. In 1936 it performed *Leiyu* (*Lei-yü; Thunderstorm*), a four-act tragedy by Cao Yu. An extremely successful playwright in the Western style, by 1941 Cao had written six important plays, including *Beijingren* (1940; *Pei-ching jen;* "Peking Man"); heavily influenced by Eugene O'Neill and Henrik Ibsen, he portrayed dissolute members of the old gentry class and new rising entrepreneur class.

Nationalism, the upheaval of World War II, and changes of government in China, Korea, and Japan between 1945 and 1949 are reflected in contemporary theatre and dance in East Asia. In China an estimated 60,000 performers were mobilized into some 2,500 propaganda troupes during the Sino-Japanese War beginning in 1937 under the direction of the well-known playwright Tian Han. Hundreds of thousands of ordinary Chinese in the army were exposed to modern forms of drama for the first time, and, equally significant, artists discovered regional folk legends, songs, and dances, which they then incorporated into their work. For example, *Baimao nü* (*Pai-mao nü; The White-Haired Girl*) was developed from northern Chinese *yang-ko* folk dances into both a ballet and an opera. The heroine, an escaped concubine of a cruel landlord, symbolized all victims of feudal governments and oppressive social systems.

At Yen-an in 1942 Mao Zedong enunciated one of the basic principles of communist art: art should have the dual function of serving the masses and of being artistically superior. In the years since the establishment of the People's Republic of China in 1949, theatre activities have swung between these goals, depending on the current ideological line of the government. Initially, the traditional opera repertoire was purged of feudal, superstitious, or otherwise ideologically incorrect material. Government policy encouraged realistic spoken drama (*hua-chü*); but, in spite of successes such as Lao She's naturalistic *Chaguan* (1957; *Ch'a-kuan;* "Teahouse"), audiences have not responded to this "foreign" form of drama. From 1964, when Jiang Qing, Mao's wife, guided the composition of the first modern revolutionary operas, in which contemporary soldiers and workers were the heroes, until 1977, traditional operas were completely banned. During the Great Proletarian Cultural Revolution (1966–76), many traditional theatre artists were denounced or imprisoned. Famous modern drama figures such as Wu Han, author of *Hai Rui baguan* (1960; *Hai Jui pa-kuan; Hai Jui Dismissed from Office*), were persecuted and their plays banned. With the fall of the Gang of Four in 1976, the traditional repertoire was reinstated once more and Jiang's "model" revolutionary operas no longer staged. During the decade-long open-door policy (1979–89), theatre contacts with the West were tentatively resumed after 40 years abeyance: Arthur Miller was invited to direct *Death of a Salesman* in 1983, and the Shanghai Kun-ch'ü Opera Company toured in Europe with its opera version of *Macbeth* in 1987. The influence of Western plays is seen in the social satire *Chia-ju wo shih chen-ti* (1979; "If I Were Real") by Sha Yexin and Gao Xingian's Artaudian *Ye ren* ("Wild Man"), initially banned, then produced in 1985.

Government policies strongly affect the economics of Chinese theatre as well as dramatic themes and forms. After the establishment of the People's Republic, professional theatre troupes received full government subsidy. Following economic liberalization policies of 1986–87, however, troupes were required to earn increasing revenues from box-office income. At the same time, urban audience attendance declined (in part because of competition from films and television), with the result that some troupes disbanded and others were reduced in size. Government-supported theatre academies in Peking, Shanghai, and regional capitals play an essential role in training young theatre artists in traditional as well as modern genres. Foreign theatre exchanges of the 1980s were welcomed by many theatre artists who wished to bring new ideas into Chinese theatre, in particular to appeal to youthful audiences who were abandoning theatre for film and television; these exchanges again were halted in 1989 in the wake of the government's suppression of the Chinese student democracy movement at Tiananmen Square.

The performing arts in Nationalist China

The Nationalist government has supported Peking opera on Taiwan since establishing the headquarters of the Republic of China on that island. Troupes of the air force and the army are active, and the Foo Hsing Opera School receives government support. Local opera (*kotsai-hsi*), sung in the Taiwanese dialect, is extremely popular in commercial theatres, and many itinerant Taiwanese troupes tour glove-puppet plays (*po-the-hi*) to towns and villages.

KOREA

In addition to folk dances, the main traditional forms that developed in Korea are ritual court dances, masked dances, and puppet plays. Of these, masked dances and masked-dance plays have perhaps the oldest and richest traditions. Archaeological evidence suggests that masks were used at least by the 3rd century AD to impersonate animal spirits and thereby placate them. Various kinds of masks—demon masks, medicine masks, spirit masks—were worn by shamans as they danced to draw into themselves the spirit being addressed, in order to cure an illness or otherwise affect daily life.

Three Kingdoms period. Lack of records makes it impossible to describe accurately dances and dance plays of Korea prior to the period of the Three Kingdoms (*c.* 57 BC–AD 668). Chinese, Japanese, and Korean accounts beginning in the 7th century give some indication of court arts in the Three Kingdoms of Koguryŏ, Paekche, and Silla (Shinla). In Koguryŏ, encompassing what is now Manchuria and northern Korea, Central Asian music and dances were combined with local styles of music and dance. Twelve of 24 pieces in the repertoire were mask dances. So highly regarded were the arts of Koguryŏ that they made up a separate Korean component of the Nine Departments of Musical Art and Dance at the T'ang court in China (25 musical and dance items were identified as Korean), and from the 7th century they were introduced into Japan, where they became the basis of *bugaku* (court masked dance). The strongly Buddhist state of Paekche in the southwest had been in contact with both China and Japan from early in the Christian era. Typical of Paekche was a Buddhist masked-dance processional (*kiak*), originating in southern China and taken to Japan in 612 by a resident of Paekche, Mimaji. No Korean account of *kiak* survives, but Japanese accounts make clear that it was performed as a Buddhist ceremonial for evangelical purposes.

Great Silla period. The third kingdom, Silla, absorbed Koguryŏ and Paekche in the 7th century, and during the Great or Unified Silla period (668–935) the folk and court performing arts of all parts of Korea intermingled. Several major types of masked dance are mentioned in Silla records. The spirit of a noble youth who died to save his father's throne was memorialized in a masked sword dance (before this time, palace dancing girls had performed sword dances, but always unmasked). Masked dances called "The Five Displays" are mentioned in a Silla poetic composition of the 9th century. They included acrobatics, ball juggling, farcical pantomime, shamanistic masked dances, and the lion dance. The similarity of several to Japanese *bugaku* dances has been noted. Others believe "The Five Displays" derive from the "hundred entertainments" of China. Finally, an important dance play honouring Ozoyong, the son of the Dragon God of the Eastern Sea, dates from this period. Ozoyong showed such generosity toward the spirit of plagues that henceforth

The dance play honouring Ozoyong

the spirit promised never to enter a household where a portrait of Ozoyong was hung. Originally derived from animistic beliefs, the dance was modified by Buddhism and was developed in the Chosŏn dynasty (1392–1910) into a spectacular dance play performed by a cast of 5 masked dancers and 16 unmasked dancing girls and accompanied by an ensemble of 37 musicians.

Koryŏ period. The two major court festivals at which performances were held during the Koryŏ period (935–1392) were Buddha's birthday, or the Feast of Lanterns, in the second lunar month, and the midwinter ceremony honouring spirits of local gods. Dances and masked plays from Silla times were carefully preserved and performed on these occasions in a specially decorated and candlelit ceremonial room. New masked plays memorializing loyal warriors who had died in battle were added from the 10th century. Buddha was offered gifts of wine and food, and performance was dedicated to maintaining a reign of peace and harmony. From the time of King Munjong (1046–83), T'ang style dances and sung dramas were performed on other occasions; modified by Korean forms, they became part of Korean court dance in centuries following.

Folk dances and plays undoubtedly go back many centuries before this; in the Koryŏ period, professional troupes also became part of urban life. The practice of court performers holding civil-service jobs in the major cities and in provincial towns probably accounts for the fact that knowledge of court performing arts began to reach beyond the confines of the court during this time. Popular troupes began the process of secularizing religious masked dances (such as the *narye,* which formerly was performed to exorcise evil). They performed acrobatics and shows of skill and at least by the 12th century were staging satiric dialogue plays that held officialdom up to ridicule. (The development of social satire is found in many Asian drama forms: the Vidusaka jester in Sanskrit drama, the god-clown-servants of Indonesian *wayang* shadow plays, and the servants of *kyōgen* comedies in Japan are major roles in these forms.)

Satiric theatre

Chosŏn and modern periods. Buddhism was rejected as a state religion by the Chosŏn (Yi) dynasty (1392–1910), with the result that court entertainments were no longer scheduled according to Buddhist days of worship but at any time court entertainment was required. A Chinese envoy to the Chosŏn court in 1488 described court performances that included the Ozoyong dragon-god dance play, children's dancing, acrobats, ropewalking, and displays of animal puppets. Following invasions by the Japanese (1592) and by the Manchu (1636), court support declined. Former palace performers formed professional troupes, in the process adapting court forms to popular tastes. These performers included all the miscellaneous

Korean female drum dance, sword dance, and masked dance, detail of a watercolour on paper scroll depicting a reception for the governor of P'yŏngyang, Chosŏn dynasty (1392–1910), by Kim Hong-do (18th century). In the National Museum of Korea, Seoul.
By courtesy of the National Museum of Korea, Seoul

stage arts in their repertoire and created from the various court dances and masked plays a type of folk masked play usually termed *sandae togam gug.* A prominent feature was the satiric treatment of depraved Buddhist monks and of grasping officials. Satiric plays were occasionally performed at court as well, but the banishment in 1504 of an actor for ridiculing the institution of kingship in a court play suggests that satire was not welcomed. *P'ansori,* a sung narrative accompanied by virtuoso drumming, was created by professional performers during the Chosŏn period. Either a man or a woman could be the solo singer-dancer, often a shaman. The current repertoire of six long stories was codified in the 19th century by the performer Shin Jae-hyo.

In addition to professional groups, villagers in different areas of the country formed folk groups to perform their own local versions of the *sandae* masked play and dances. Today the *sandae* masked play is performed by villagers in Yangju, Kyŏnggi province, and in South Kyŏngsang province in South Korea and in Pongsan, Hwanghaedo province, North Korea. Performers are males. Masks cover either the whole head or the face and are made from paper or gourds or, occasionally, are carved from wood. They are boldly painted to represent the stock characters of the play: monks, shaman, noblemen, young dancing girl, and others. There may be 20 or 30 masks used; often they are burned and made anew each year to ensure their ritual purity. Performance encompasses singing, dancing, pantomime, and dialogue. The stories enacted vary with the village, but common scenes include offerings to the gods, criticism of venial Buddhist priests, exposure of corruption by gentry and officials, flirtation, and a funeral service that brings absolution. Performances may be given as a rainmaking rite.

Song Kee-yep

The scene of *Aesadang-nori* from Yangju *sandae* mask-dance drama of Korea.

Puppet plays

In the Koryŏ period puppet plays were widely performed and very popular among the people. Several types of puppet play developed in Korea. The folk puppet play *Kkoktukaksi,* named after the wife of the main character, is still performed in the summer months in South Korea by farmers in troupes of six or seven players and musicians. Twelve or 15 puppets make a set; they are glove-and-stick figures that can be manipulated by a single puppeteer. One play, with variations, is performed. It consists of eight relatively independent scenes that satirize a figure

of the gentry who is the major character. Scenes satirizing depraved monks and insulting the gentry, a domestic triangle, and Buddhist prayers for the dead appear to be adapted from masked plays.

Gu gug (literally "old plays") became popular about the middle of the 19th century. They were dramatic songs, danced to gestures and simple group movements. Troupes played throughout the countryside and in the National Theatre, built in Seoul by the government in 1902. Until the 1930s, variety programs of *gu gug* and female court dances were popular entertainments at commercial theatres in the city. Sentimental melodramas, called "new school," or *shimpa*, plays (the same name as in Japan), were performed by a dozen troupes that formed and disbanded between 1908 and about 1930. The new school movement was begun by the novelist Yi Injik. Other major figures had learned the style while studying in Japan. In 1931 the actor Hong Haesŏng and others organized the first drama and cinema exhibition in Korea; later that year its organizers formed the Society for the Study of Dramatic Art, which studied and staged translations of modern European plays. It was active until 1939, when it was suppressed by the Japanese colonial government. Nonetheless, by 1940 about 100 amateur groups were using realistic "new drama" (*singgug*) as a means of social and political protest.

Since World War II. In Korea after 1940 all dramatic groups were obliged to belong to the Japanese-organized Dramatic Association of Korea. Many groups survived the war with Japan by touring small towns and villages. Performances lagged immediately after World War II because of unsettled conditions. A new National Theatre was established in Seoul just before the Korean War began; national support included subsidies for performances. In both North and South Korea virtually all theatres were destroyed by the war. Excellent theatres were constructed in the 1970s and '80s, however, and performances are numerous in both political areas.

In South Korea the National Theatre supports large-scale musical dramas, folk dance, and traditional music through performance and troupe subsidies. Among semiprofessional little theatre groups the Drama Center, Jayu (Free), Minye (Folk), Silhom (Experimental), and Kagyŏ (Bridge) theatre troupes are well established. Social problems and the integration of traditional and modern ways are common themes in contemporary plays. Western-style opera, ballet, and modern-dance troupes also perform.

Plays in North Korea are required to represent socialist construction, be nationalistic, and offer the masses pleasure, following the precepts of "self-reliance" (*juche*) of President Kim Il-sung (1912–94). A small number of "model" works emphasizing music or dance within grandiose spectacles ("Song of Glory" has a cast of 5,000) make up the repertoire of major theatres.

JAPAN

Among the most varied and technically complex theatre arts in Asia are those of Japan. Music and dance gradually evolved into highly developed dramatic and theatrical forms, the most important of which are nō dance drama, popular kabuki theatre, and bunraku puppet drama.

Formative period. From prehistoric times, dances have served as an intermediary between man and the gods in Japan. *Kagura* dances dedicated to native deities and performed at the Imperial court or in villages before local Shintō shrines are in essence a symbolic reenactment of the propitiatory dance that lured the sun goddess Amaterasu from the cave in ancient myth. Although *kagura* dance has been influenced by later more sophisticated dance forms, it is still performed much as it was 1,500 years ago, to religious chants accompanied by drums, brass gongs, and flutes. At the same time, villagers had their rice-planting dances, performed either at New Year's as a prayer for good planting or during the planting season in early summer. These lively dances were later, in the 14th century, brought to the cities and performed as court entertainment and called *dengaku* ("field music").

7th to 16th centuries. A massive influx into Japan of Chinese and Korean arts and culture occurred between the 6th and the 10th centuries. It has been noted that a Korean performer, Mimaji (Mimashi in Japanese), brought the Buddhist *gigaku* processional dance play to the Japanese court in 612. Mimashi established an official school to train Japanese dancers and musicians in *gigaku*. Other Korean and Chinese performers from Paekche and Koguryŏ were invited in following years. *Gigaku* masks cover the entire head (as do Korean folk masks today). Carved of wood and painted with lacquer, the 223 masks that remain (most in the Shōsō Temple in Nara) date back as early as the 7th century. They are superb examples of the art of mask making, strong-featured and beautifully conceived. From a description of a 13th-century performance, *gigaku* apparently consisted of a succession of scenes enacted as characters passed by. Masks characterized an Aryan-featured dignitary called Baramon (or Brahman, indicating Indian origin), a fierce wrestler, a Buddhist monk, a princess of the state of Wu in China, a bully, a wistful old man, and others. Some scenes were serious, others were earthy slapstick.

The *gigaku* processional dance play

Bugaku court dances introduced from Korea also were patronized by the court. They supplanted *gigaku* as official court entertainment, and *gigaku* disappeared as a performing art by the 12th century. It was the custom to have performers of *bugaku* enter from dressing rooms to the right and the left of the raised platform stage: "right" dances, costumed in orange or red, were those from India, Central Asia, or China proper; "left" dances, costumed in blue-green, were those from Korea and Manchuria. *Bugaku* is usually performed by groups of four, six, or eight male dancers who move in deliberate, stately steps, repeating movements in the four cardinal directions. Musical accompaniment is by drums, bells, flute, lute, and *shō* (panpipe). A composition consists of three sections: introduction, development, or "scattering," and speeding up (*jo-ha-kyū*). Japanese performers and courtiers created new compositions within the old style in the 10th and 11th centuries. Still, *bugaku* represents a remarkable preservation of ancient Chinese, Indian, and Korean music and dance that have long since disappeared in their countries of origin. *Bugaku* has been performed by musicians attached to the Imperial court and to major Shintō shrines from the 7th century without break to the present day.

Performance of *bugaku* court dances

Juggling, acrobatics, ropedancing, buffoonery, and puppetry—the "hundred entertainments" of China and called *sangaku*, "variety arts," in Japan—became widely popular as well. During the Heian period (794–1185) professional troupes, ostensibly attached to temples and shrines to draw crowds for festival days, combined these lively stage arts, now called *sarugaku* (literally, monkey or mimic music), with dancing to drums from *dengaku* and began to perform short plays consisting of alternate sections of dialogue, mimicry, singing, and dancing. Sometime in the 14th century a *sarugaku* actor from Nara named Kan'ami incorporated in his plays a chanted dance (*kuse-mai* or *kōwaka-mai*), for the first time creating the possibility of dramatic dance that could carry forward a story. This

Bugaku, a court dance adapted to Japanese tastes from the dance and music of 8th-century China and Korea.

fusion of dance, drama, and song, which soon came to be known as *sarugaku-no-nō*, or simply nō, marked a revolutionary advance in Japanese theatrical art. Kan'ami's son, Zeami, refined the style of performance, composed 50 or more of the finest nō plays in the repertoire, and wrote fundamental treatises on the art of acting and dramaturgy.

When Zeami was 11, the military ruler of Japan, the shogun Ashikaga Yoshimitsu, saw him perform, became enamoured of the boy's beauty, and took him into his residence in Kyōto as a companion. For most of his life, Zeami benefited from the patronage and the refined audiences that stemmed from this circumstance.

Nō theatre

The borrowings of nō from other arts are many. The exquisite masks for which nō theatre is famous have a quality of serenity, a neutrality of expression that places them in a rank perhaps unmatched in the world. Yet, historically there is no doubt that they are derived from earlier *bugaku* and *gigaku* masks and hence are related, if distantly, to the masks of Korea, China, and India. One evidence of the special development of nō masks is that they are smaller than previous masks; they cover only the face proper. From *bugaku* music, Zeami took the three-part structure of the nō drama. A normal nō program consists of five plays, which are grouped into three dramatic units: the introduction, the development, and the conclusion. The first play, a "god" play, constitutes the introduction; the second drama, or "warrior" play, is the introduction of the development section; the third, or "woman," play is the development of the development; the fourth, or "living person," play is the conclusion of the development; and the fifth, or "demon," play is the conclusion. Drums and flute were taken over from earlier musical forms, and nō chanting grew out of Buddhist prayer chants. The songs' poetic meter of alternating phrases of seven and five syllables had come from China six centuries earlier and was the standard Japanese poetic form. On the other hand, the nō stage represents an advance on the simple square platform of *bugaku*. A sharply peaked roof over the stage is supported by four pillars—to help the performer orient himself as he looks out through tiny eye holes in the mask—and a long ramp, *hashigakari*, emphasizes the entrance of major characters.

Typical of a number of nō plays that are dramatizations of Chinese history and legends is the 15th-century *Yōkihi*, by Komparu Zenchiku, based on the 9th-century narrative poem *Ch'ang hen ko* ("The Song of Everlasting Sorrow") by Po Chü-i. The original describes Emperor Hsüan-tsung's love for his concubine Yang Kuei-fei (Yōkihi in Japanese). The nō play emphasizes the Buddhist sentiment of the evanescence of mortal life and the inevitability of pain and sadness. Every nō play contains Chinese poems, quoted verbatim or paraphrased so as to appeal to the educated spectator. It was a first principle of dramatic writing, said Zeami, to base a play on a well-known incident in which the central character was familiar to the audience. Zeami's plays emphasized the quality of restrained beauty (*yūgen*), a concept derived in part from Zen Buddhism. Later plays, especially those by Kanze Kojirō Nobumitsu (1435–1516), such as *Momijigari* (*The Maple Viewing*) and *Ataka* (*The Ataka Barrier*), emphasize action and spectacle (*fūryū*).

The *kyōgen* farce comedy

On the usual nō program, each play was followed by a *kyōgen* farce comedy. The antecedents of *kyōgen* cannot be described with certainty, but it is probable that *kyōgen's* short sketches of master-servant quarrels, husband-wife arguments, animal fables, and scenes of rustic life derive from early *sangaku* entertainments. A few *kyōgen* plays are accompanied by the drums and flute of nō. The ritual play *Okina*, performed as an auspicious prayer for longevity at the beginning of a nō-*kyōgen* program, is in both repertoires, and some suggest that the *kyōgen* version is the older. The style of *kyōgen* music (*koutai*) is distinct from that of nō music; it is derived directly from popular songs. *Kyōgen* plays with music are, however, a rarity. The usual play is a straight dialogue drama, making it perhaps the oldest developed form of nonmusical play in East Asia. Dialogue is composed in colloquial language of the 15th century, in short phrases suitable for comedy. Movement is highly stylized, again for comic effect. Masks may be worn for the roles of animals and demons, but most roles are played unmasked. *Kyōgen* texts do not seem to have been committed to writing until the 16th century, suggesting that actors traditionally ad-libbed their parts. Today *kyōgen* actors commit lines to memory.

Azuchi-Momoyama period. Nō and *kyōgen* were dance and theatre forms that had come to express the gravity and decorum of a rigidly formal samurai ruling class by the end of the Azuchi-Momoyama period (1574–1600). Artistically severe and highly disciplined, nō was imbued with the sternly pessimistic philosophy of Buddhism. In content, nō plays taught the folly of worldly power and position, that time destroys all living things. The heroes of play after play pray for the divine intercession of Amida (Amitābha) in order that they, tormented ghosts of dead warriors and court ladies, may break free of earthly attachments and achieve Buddhist salvation. In contrast to this,

The *hayashi* (musicians) are seated in front of the pine tree painted on the *kagami-ita* (rear wall); the *jutai* (chorus) sits at right; and a *kokeu* (stage assistant) sits at the left. A portion of the *hashigakari* (ramp leading to stage) is at far left.

commoners of the cities in the late 16th century began to perform their own dances and plays that were up-to-date, lively, exciting, and at times morally licentious. They were intended to appeal to literate townsmen, well-to-do wives of merchants, workers, and the fops, wits, and dandies of the burgeoning cities.

Tokugawa period. During the Tokugawa period (1603–1867) nō was assiduously cultivated by samurai as a refined accomplishment. Commoners were forbidden by law to study nō and were excluded from performances except on special "subscription" occasions, when any person, high or low in rank, could see nō performed outdoors in a large enclosure. Nō became the exclusive theatre art of the warrior class, while *bugaku* continued as the chief performing art of the Imperial court.

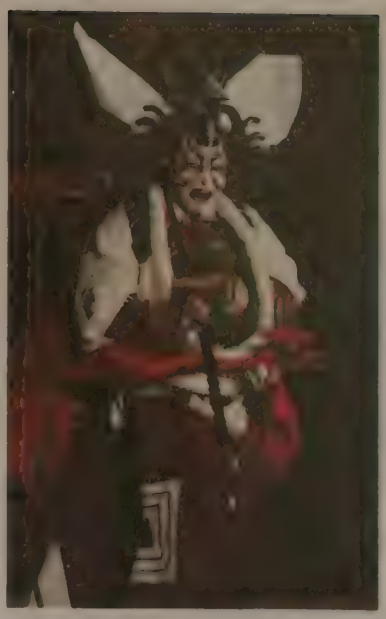
The earliest important urban entertainments of the commoner in Japan were secularized forms of Buddhist dance plays (*ennen*) and folk dances (*yayako odori* and *kaka odori*) that came to be called *fūryū* ("drifting on the wind") dances. They were enormously popular.

Origin of kabuki

In 1603 several kinds of urban dances were arranged by a young woman named Okuni into a new dance, called kabuki. Other troupes of female prostitute-performers adopted the sensuous and popular style of Okuni's kabuki dance. A scroll of the period shows Okuni as a young, fashionably dressed samurai, indolently leaning on a sword, dallying with a teahouse girl. Around her neck hangs a Christian crucifix, not as a religious article but as an exotic decoration recently introduced by "southern barbarian" Portuguese merchants. Other pictures of the time show young women playing the three-stringed samisen as they recline sensuously on tiger skins, dancing girls circling about them. Audiences of monks, warriors, young lovers, and townsmen gaze raptly at this appealing and even bizarre sight. The original sensuous appeal of women's kabuki continued long after women were banned from the stage in 1629. From about Okuni's time until 1652, troupes of boy prostitutes performed graceful kabuki dances to samisen music to attract customers. The appearance of professional women and boy performers in kabuki was a phenomenon of urban society.

In 1653, when the authorities required kabuki to be performed by adult males, kabuki began to develop as a serious art. During the Genroku era (1688–1703), most of kabuki's essential characteristics were established. Large, commercial theatre buildings holding several thousand spectators were constructed in the three major cities—Edo (Tokyo), Kyōto, and Ōsaka. The stage, which previously had been simply a copy of the nō stage, became wider and deeper and was equipped with a draw curtain to separate acts; and in the early 1700s a ramp (*hanamichi*) was constructed from the rear of the auditorium to the stage for actors' entrances and exits. The idea of the rampway came from the nō *hashigakari*, but, in typical kabuki fashion, it was transformed into an infinitely more theatrical device. From the puppet theatre, kabuki borrowed the use of fairly elaborate scenery, the revolving stage (100 years before its use in Europe), traps, and lifts. To the old nō drums and flute were added the new samisen, a large drum, a dozen bells, cymbals, gongs, and two types of wooden clappers, making the resulting music flexible and varied.

Nō and *kyōgen* plays were often performed as kabuki in the early decades. A print from about 1670 shows kabuki actors performing *Sumidagawa* (*The Sumida River*), with costumes and properties modeled closely on the nō original. But it was not considered proper for "beggars of the riverbed" to stage the art of the warrior class. By Genroku times, new kabuki dramatic styles had emerged. The actor Sakata Tōjūrō (1647–1709) developed a relatively realistic, gentle style of acting (*wagoto*) for erotic love stories in Kyōto, while in Edo, a stylized, bravura style of acting (*aragoto*) was created by the actor Ichikawa Danjūrō I (1660–1704) for bombastic fighting plays. In the play *Sukeroku yukari no Edo zakura* (*Sukeroku: Flower of Edo*) written by Tsuuchi Jihei II in 1713, the two styles are blended most successfully. The hero, Sukeroku, is a swaggering young dandy and lover acted largely in the Edo style, while Sukeroku's brother, Shimbei, is a meek, gently comic foil in the Kyōto style. Genroku-period kabuki



A classic *mie* in the *aragoto* style. Ichikawa Danjūrō XII in the role of the warrior hero in *Shibaraku*, a kabuki play written by Ichikawa Danjuro I and first performed in 1697.

plays are lusty and active and contain much verbal and physical humour.

Kabuki theatres were required to be built in special entertainment quarters (near licensed quarters for prostitution), along with puppet theatres. Puppets, imported from Korea centuries earlier, were fused with epic storytelling and the resulting narrated play accompanied by samisen music sometime before 1600. The earliest tales were about the princess Jōruri (hence, *jōruri* as another name for puppet plays). This and other legends were in the nature of Buddhist miracle stories, the obligatory scene being one in which Buddha sacrifices himself or otherwise brings to life one of the main characters. Simple doll puppets, held overhead by one man, animated these blood-and-thunder *kojōruri* ("old *jōruri*") puppet plays.

The role of Chikamatsu in the puppet theatre

A new style of puppet play was created in 1686 by the writer Chikamatsu Monzaemon (1653–1725) and the chanter Takemoto Gidayū at the Takemoto Puppet Theatre in Ōsaka, the city which became the home of puppet theatre in Japan. The chanter is responsible not only for narrating the play but for providing the voices of all the puppet characters as well; Gidayū's expressive delivery style remains influential to this day. Chikamatsu went on to become Japan's most famous playwright. Although he is best known for his puppet plays, he wrote kabuki plays as well, most of them for Sakata Tōjūrō. From Tōjūrō, Chikamatsu learned the soft style of kabuki performance and the situation that is so unique to early kabuki, in which a comic lover visits a courtesan in the licensed quarter and quarrels with her. Between *Sonezaki shinjū* (*Love Suicides at Sonezaki*), written in 1703, and *Shinjū ten no Amijima* (*Love Suicides at Amijima*), written in 1721 three years before his death, Chikamatsu composed for the puppet theatre a dozen domestic tragedies handling the theme of lovers' suicide. As early as 1678, kabuki plays were dramatizing current city scandals, lovers' suicides, murders, and tragic deaths. One of the most characteristic features of kabuki was its contemporaneous dramatic subject matter; puppet drama was much changed when Chikamatsu brought this quality from kabuki into his puppet plays.

The puppet theatre underwent significant physical change when the puppet operators, samisen player, and chanter were made fully visible to the audience in 1705. In the 1720s and '30s puppet plays gradually became more dramatic and less narrative under the influence of kabuki. A revolutionary three-man puppet was created in which

mouth, eyes, eyebrows, and fingers could move, encouraging writers to compose dramatic plays calling for complex emotional expression. A theatre manager and writer, Takeda Izumo II (1691–1756), collaborated with several other authors on all-day history plays, the so-called "Three Great Masterpieces" of puppet drama: *Sugawara denju tenarai kagami* (1746; *The Secret of Sugawara's Calligraphy*), *Yoshitsune sembonzakura* (1747; *Yoshitsune and the Thousand Cherry Trees*), and *Kanadehon chūshingura* (1748; *Chūshingura: The Treasury of Loyal Retainers*). The latter is the best-loved and most often performed drama ever written in Japan; it typifies mature puppet drama. It is based on actual events that occurred from 1701 to 1703: 46 retainers avenged the death of their lord by killing his enemy and were then sentenced to commit *seppuku,* or ritual suicide by disembowelment. (A 47th conspirator was not involved in the actual killing.) The major scenes of the suicides of the lord Hangan and his retainer Kampei are intensely emotional scenes of self-sacrifice. Such scenes normally occur as the final section of the third act in a five-act history play and are called *sewa* ("family") scenes because, although the figures are samurai, tearful family separation is the emphasis of the scene. *Ichinotani futaba gunki* (1751; *Chronicle of the Battle of Ichinotani*) contains a *migawari* ("child substitution") scene, typical of puppet history plays, which is, if anything, even more tear-provoking: in response to the wishes of his lord Yoshitsune, General Kumagai slays his own son, so that the son's head may be substituted for that of a prince who has been condemned to die. Although the puppet plays' emotionalism and lack of humour were foreign to kabuki, the serious dramas were so popular with audiences that they were adopted, with changes, to kabuki. Today the best puppet plays are equally a part of the kabuki and puppet theatre repertoires.

19th-century kabuki plays

During the 19th century the most important kabuki dramas were written in Edo, by Tsuruya Namboku IV and Kawatake Mokuami. They wrote all the standard types of kabuki play—*sewamono* (domestic), *jidaimono* (history), and *shosagoto* (dance plays)—in large numbers; each wrote between 150 and 200 plays in his professional career. They spent their lives in the kabuki theatre as writers. Although neither was formally educated, their plays reflect with great discernment the desperate social conditions that prevailed as the feudal system in Japan neared its collapse. Thieves, whores, murderers, pimps, and ruthless masterless samurai are major figures in a new type of play, *kizewamono,* or gangster play, which Namboku created and Mokuami developed. They wrote for the talents of star actors: Namboku wrote for the finest *onnagata* (female impersonator) of his time, Iwai Hanshirō V, and Mokuami wrote for Ichikawa Danjūrō IX and a remarkable actor of gangster roles, Ichikawa Kodanji IV. Each was a master of kabuki art, and between them they added new dimensions to kabuki's stylized form. Namboku created rhythmic dialogue composed in phrases of seven and five syllables; Mokuami used puppet-style music to heighten the pathos of certain scenes and wrote elaborately conceived major speeches which required exceptional elocutionary skill on the part of the actor.

Meiji period. Nō, puppet theatre, and kabuki were affected in differing degrees by the abolition of feudalism in 1867. At a stroke, the samurai class was eliminated and nō lost its base of economic support. Important actors retired to the country to eke out a living as menial workers. For several years nō was not performed at all, except that Umewaka Minoru, a minor actor, gave public performances in his home and elsewhere between 1868 and 1876. In 1881 a public stage was built in Shiba Park, Tokyo, for performances sponsored by the newly formed Nō Society and by its successor, the Nō Association. The most influential supporter of nō during the Meiji period (1868–1912) was the aristocrat Iwakura Tomomi. The study of nō came to be a highly regarded activity among the middle classes, and in time each of the five nō schools (Kanze, Hōshō, Komparu, Kongō, and Kita) became financially stable, sponsoring their own performances and building their own theatres in the major cities.

The end of feudal society forced nō to seek and cultivate a new audience; the popular audience of kabuki and the puppet theatre, however, continued with little change during the Meiji period. Kabuki audiences remained large and loyal, but audiences for puppet plays continued to decline as they had for the previous hundred years. There was a brief revival of interest in Ōsaka puppet drama in the 1870s under the impetus of the theatre manager Daizō, the fourth Bunrakuken, who called his theatre Bunrakuza (from the name of a troupe organized by Uemura Bunrakuken early in the century). The popular term for puppet drama, bunraku, dates from this time. Learning to chant puppet texts became a vogue during the late Meiji period. In 1909 the Shōchiku theatrical combine supported performances at the Bunraku Puppet Theatre in Ōsaka, and by 1914 this was the only commercial puppet house remaining.

As they always had, kabuki writers and actors of the Meiji period tried to place current events on the stage. Thus, the actor Onoe Kikugorō V began acting in a series of contemporary plays, dressed in daily kimono or Western clothes and with his hair cut Western fashion (the origin of *zangirimono,* or the so-called "cropped-hair plays"), in the late 19th century. Western influence also was seen in theatre construction, with the first European-style theatre built for kabuki in Tokyo in 1878. Released from previous government restrictions, kabuki artists created dance dramas from the nō play *The Maple Viewing* and others, in which the elevated tone of the nō original was purposely retained. Kabuki attendance was more than a million

Bunraku, a scene from the comedy *Tsuri onna* ("Fishing for a Wife"), a puppet performance of a kabuki dance version of the *kyōgen* original play. Chief puppeteers wear conventional dress, minor puppeteers wear black, hooded costumes. Pine-and-plank scenery indicates the nō-*kyōgen* origin of the play.

spectators yearly. But, in spite of prosperity and seeming adaptation to new conditions, by the early decades of the 20th century, new artistic creation in kabuki reached an impasse, and thereafter kabuki became restricted almost as much as bunraku and nō to a classic repertoire of plays.

Scholars and artists, learning of Western drama, organized successive groups designed to reform kabuki—that is, to eliminate excessive stylization and to press for a more realistic manner of performance. The actor Ichikawa Danjūrō IX acted in historically accurate (and reportedly dull) *katsureki geki* ("living history" plays) written by the journalist Fukuchi Ōchi. Three *shin* kabuki ("new kabuki" plays) written by the scholar Tsubouchi Shōyō were influenced by Shakespeare, whose plays Tsubouchi was then translating. In 1908 a young actor, Ichikawa Sadanji II, returned from a year's study and observation in Europe. These and other influences produced few long-lasting changes in kabuki, but they did set the stage for the creation of new kinds of drama that would depart radically from traditional forms.

Contributions of Kawakami

The first plays in Japan consciously based on Western models were those arranged and acted in by Kawakami Otojirō. Kawakami's first plays were political and nationalistic in intent. After he and his wife Sada Yakko had performed in Europe and America (1899 and 1902), they introduced to Japan adaptations of Shakespeare, Maurice Maeterlinck, and Victorien Sardou. These *shimpa,* or "new school," plays, however, were little more than crude melodramas. Yakko and other actresses performing in *shimpa* marked the first time women had appeared on the professional stage since Okuni's time. One *shimpa* troupe continues to perform today, in a style that retains turn-of-the-century sentiment and mannerisms.

In 1906 the Literary Society was established by Tsubouchi Shōyō to train young actors in Western realistic acting, thus beginning the serious study of Western drama. The first modern play (*shingeki*) to be staged in Japan in the Western realistic manner was Ibsen's *John Gabriel Borkman,* directed by Osanai Kaoru in 1909 at his Free Theatre, which was modeled on the "free theatres" of Europe. Much to the detriment of *shingeki*'s development, major European playwrights—George Bernard Shaw, Anton Chekhov, Leo Tolstoy, Gerhart Hauptmann, Maeterlinck—were chosen for production over aspiring Japanese authors by all the important early troupes: the Art Theatre (1913–19) founded by a Tsubouchi disciple, Shimamura Hōgetsu; the Stage Association; and the Tsukiji Little Theatre (1924–28). The members of *shingeki* troupes were earnest amateurs, strongly motivated by artistic and social ideals to create a theatre that reflected life in 20th-century Japan. The only early *shingeki* troupe to survive World War II was the Literary Theatre (1937).

Since World War II. Following Japan's surrender in 1945, kabuki and bunraku plays that the American occupation forces considered feudal, such as *Kanjinchō* (*The Subscription List*) and *Chūshingura: The Treasury of Loyal Retainers,* were banned briefly. Since then, nō and kabuki have greatly prospered, while bunraku has become increasingly subsidized. Modern drama authors and performers, many of whom had been jailed or persecuted by Japanese authorities during World War II for liberal and leftist beliefs, were encouraged by the occupation forces. Important *shingeki* troupes founded in the immediate postwar years include the Actors' Theatre (1944), directed by Senda Koreya, an expert on the works of Bertolt Brecht; The People's Theatre, devoted to progressive social and political issues; and Theatre Four Seasons (1953), which specialized first in French drama and later in American musicals. The full range of Japanese modern life was examined in such *shingeki* plays as Kinoshita Junji's nostalgic folk drama *Yūzuru* (1949; *Twilight Crane*); Mishima Yukio's psychological study of cruelty *Sado koshaku fujin* (1965; *Madame de Sade*); Tanaka Chikao's *Maria no kubi* (1959; *The Head of Mary*), about the atomic bombing of Hiroshima; the Social Realist play *Kazanbaichi* (1938; *Land of Volcanic Ash*) by Kubo Sakae; and Inoue Hisashi's comic tribute to popular theatre, *Keshō* (1983; "Makeup").

Shingeki's orthodox realism, its increasing commercialism, and its impotence during the struggle to block the 1960 passage of the United States–Japan Treaty of Mutual Cooperation and Security alienated younger theatre artists. In the 1960s, for both political and artistic reasons, director-authors Suzuki Tadashi, Terayama Shūji, Kara Jūrō, and Ohta Shōgo formed their own acting companies in order to create unique new theatrical works incorporating stylized acting, song, dance, and brilliant stage effects. They believed that it was necessary to turn back to traditional Japanese culture and arts in order to move forward toward a Japanese theatre unfettered by Western models. Social disjuncture and alienation are common themes of the absurdist plays *Tomodachi* (1967; *Friends*), by Abe Kōbō, Betsuyaku Minoru's *Zo* (1962; *The Elephant*), and Satoh Makoto's *Atashi no Beatles* (1967; *My Beatles*).

The most extreme rejection of both Western mimesis and traditional Japanese aesthetics is seen in *butō* (or *ankoku butō,* "dance of darkness"), a postmodern movement begun by Hijikata Tatsumi and Ohno Kazuo in the 1960s in which formal dance technique is eschewed and primal sexuality and the grotesque are explored. The *butō* troupes Sankaijuku, Dairakudakan, and Byakko-sha, as well as individual dancers such as Tanaka Min, often tour Europe and the United States.

In some ways the effects of modernization on the performing arts in 20th-century Japan have been great. In the 1950s the country's motion-picture industry was the second largest in the world, only to be displaced by television, which saturated every corner of Japan by the end of the 1960s. Yet attendance for live theatre did not decline; on the contrary, in the general affluence of Japanese society of the 1970s and '80s, attendance continued to grow at almost every type of performance. Overall in Tokyo, some 3,000 live theatre productions are staged annually, and a boom in theatre building has added scores of elegant new playing spaces for both traditional and avant-garde performance. Nō and kabuki dance are avidly studied by thousands of amateurs; three new national theatres (built 1966–85) house subsidized productions of nō, kabuki, and bunraku; lavish theatre and dance festivals annually host local and foreign troupes; and international tours regularly introduce Japanese plays and dances to foreign audiences. Live theatre of all types flourishes in Japan, each form appealing to its own sector of the overall audience.

(1954–68), a collection of calligraphy; JEROME SILBERGELD, "Chinese Concepts of Old Age and Their Role in Chinese Painting, Painting Theory, and Criticism," *Art Journal,* 46(2):103–114 (Summer 1987), "Chinese Painting Studies in the West: A State-of-the-Field Article," *Journal of Asian Studies,* 46(4):849–897 (1987), and *Chinese Painting Style* (1982); OSVALD SIRÉN, *Chinese Painting: Leading Masters and Principles,* 7 vol. (1956–58, reissued 1974); MICHAEL SULLIVAN, *The Birth of Landscape Painting in China,* 2 vol. (1962–80), and *Chinese Landscape Painting: The Sui and T'ang Dynasties* (1980); FRITZ VAN BRIESSEN, *The Way of the Brush: Painting Techniques of China and Japan* (1962, reissued 1978); MARSHA WEIDNER (ed.), *Flowering in the Shadows: Women in the History of Chinese and Japanese Painting* (1990); and YU FEIAN (FEI-AN YÜ), *Chinese Painting Colors: Studies on Their Preparation and Application in Traditional and Modern Times,* trans. from Chinese by JAMES SILBERGELD and AMY MCNAIR (1988).

Decorative arts are presented in NANCY ZENG BERLINER, *Chinese Folk Art: The Small Skills of Carving Insects* (1986); JESSICA RAWSON and JOHN AYERS, *Chinese Jade Throughout the Ages* (1975); OSVALD SIRÉN, *Chinese Sculpture from the Fifth to the Fourteenth Century,* 4 vol. (1925, reprinted 1970); ZHOU ZUN (HSÜN CHOU) and GAO CHUNMING (CH'UN-MING KAO), *5000 Years of Chinese Costumes* (1987; originally published in Chinese, 1984); and WANG SHIXIANG (SHIH-HSIANG WANG), *Classic Chinese Furniture: Ming and Early Qing Dynasties* (1986; originally published in Chinese, 1985).

Analyses of 20th-century arts include JOAN LEBOLD COHEN, *The New Chinese Painting, 1949–1986* (1987); ROBERT HATFIELD ELLSWORTH, *Later Chinese Painting and Calligraphy, 1800–1950,* 3 vol. (1987); ELLEN JOHNSTON LAING, *The Winking Owl: Art in the People's Republic of China* (1988); CHU-TSING LI, *Trends in Modern Chinese Painting* (1979); JEROME SILBERGELD and GONG JISUI (JISUI GONG), *Contradictions: Artistic Life, the Socialist State, and the Chinese Painter Li Huasheng* (1993); and MICHAEL SULLIVAN, *Chinese Art in the Twentieth Century* (1959), and *The Meeting of Eastern and Western Art,* 2nd ed. (1989). (Je.Si.)

Korea: Survey studies include ANDREAS ECKARDT, *A History of Korean Art* (1929; originally published in German, 1929); CHEWŎN KIM and WON-YONG KIM (eds.), *Korean Arts,* 3 vol. (1956–63); CHEWŎN KIM and WON-YONG KIM, *Treasures of Korean Art* (1966); EVELYN MCCUNE, *The Arts of Korea* (1962); *The Arts of Korea,* 6 vol. (1979), on prehistoric art, painting, Buddhist art, ceramics, handicrafts, and architecture; CHEWŎN KIM and LENA KIM LEE (I-NA KIM), *Arts of Korea* (1974); YI KI-BAEK (KI-BAEK YI), *5,000 Years of Korean Arts* (1976); KIM WON-YONG (WON-YONG KIM), *Art and Archaeology of Ancient Korea* (1986); and KIM WON-YONG (WON-YONG KIM) *et al., Korean Art Treasures* (1986), a survey of the history of Korean art by Korean experts. Three useful exhibition catalogs are NATIONAL GALLERY OF ART (U.S.), *Masterpieces of Korean Art* (1957); ARTS COUNCIL OF GREAT BRITAIN, *An Exhibition of National Art Treasures of Korea* (1961); and RODERICK WHITFIELD (ed.), *Treasures from Korea: Art Through 5000 Years* (1984), with excellent introductions. Studies of ceramics include ROBERT P. GRIFFING, JR., *The Art of the Korean Potter* (1968), with an excellent introduction; G.ST.G.M. GOMPERTZ, *Korean Celadon, and Other Wares of the Koryŏ Period* (1963); W.B. HONEY, *Corean Pottery* (1947, reissued 1955); and CHEWŎN KIM and G.ST.G.M. GOMPERTZ (eds.), *The Ceramic Art of Korea* (1961). (W.-Y.K.)

Japan: A comprehensive single-volume survey of Japanese art is PENELOPE MASON, *History of Japanese Art* (1993). Serviceable introductions are found in JOAN STANLEY-BAKER, *Japanese Art* (1984); and ROBERT TREAT PAINE and ALEXANDER SOPER, *The Art and Architecture of Japan,* 3rd ed. (1974). Two multivolume series are noteworthy: *The Heibonsha Survey of Japanese Art,* 31 vol. (1971–80); and *Japanese Arts Library* (1977–), are translations and adaptations of Japanese originals, featuring both site-specific and thematic studies. LAURANCE P. ROBERTS, *A Dictionary of Japanese Artists* (1976, reissued 1990), is an indispensable compendium of artists' biographies. *Kodansha Encyclopedia of Japan,* 9 vol. (1983), provides an excellent selection of general and specific articles on Japanese art. SHERMAN E. LEE, *A History of Far Eastern Art,* 5th ed. edited by NAOMI NOBLE RICHARD (1994), relates Japanese art to the wider East Asian context.

The development of Japanese art from Paleolithic times to the 7th century is summarized and related to Chinese and Korean material by GINA L. BARNES, *China, Korea, and Japan: The Rise of Civilization in East Asia* (1993). Other works treating the pre-Buddhist period include RICHARD J. PEARSON *et al., Ancient Japan* (1992); JAPAN, BUNKACHŌ and JAPAN SOCIETY (NEW YORK, N.Y.), *The Rise of a Great Tradition: Japanese Archaeological Ceramics of the Jōmon Through Heian Periods (10,500 BC–AD 1185)* (1990); and J.E. KIDDER, JR., *Japan Before Buddhism,* rev. ed. (1966).

Works that treat the complexity of Buddhist art development include KURATA BUNSAKU (BUNSAKU KURATA), *Hōryū-ji: Temple of the Exalted Law,* trans. from Japanese (1981); JIRŌ SUGIYAMA, *Classic Buddhist Sculpture,* trans. from Japanese and adapted by SAMUEL CROWELL MORSE (1982); YUTAKA MINO *et al., The Great Eastern Temple: Treasures of Japanese Buddhist Art from Tōdai-ji* (1986); NISHIKAWA KYŌTARŌ (KYŌTARŌ NISHIKAWA) and EMILY J. SANO, *The Great Age of Japanese Buddhist Sculpture, AD 600–1300* (1982); JŌJI OKAZAKI, *Pure Land Buddhist Painting,* trans. from Japanese and adapted by ELIZABETH TEN GROTENHUIS (1977); and HISATOYO ISHIDA, *Esoteric Buddhist Painting* (1987; originally published in Japanese, 1969). Other important sources are MIYEKO MURASE, *Emaki: Narrative Scrolls from Japan* (1983); VICTOR HARRIS and KEN MATSUSHIMA, *Kamakura: The Renaissance of Japanese Sculpture, 1186–1333* (1991); and JAN FONTEIN and MONEY HICKMAN, *Zen Painting and Calligraphy* (1970).

The expression of indigenous religion and its relation to Buddhism is summarized in HARUKI KAGEYAMA, *The Arts of Shinto,* trans. from Japanese and adapted by CHRISTINE GUTH (1973). YOSHIAKI SHIMIZU and JOHN M. ROSENFIELD, *Masters of Japanese Calligraphy: 8th–19th Century,* ed. by NAOMI NOBLE RICHARD (1984), discusses the cornerstone of East Asian visual expression.

Daimyo and shogunal patronage from the 15th century is summarized in JAY A. LEVENSON (ed.), *Circa 1492: Art in the Age of Exploration* (1991); and YOSHIAKI SHIMIZU (ed.), *Japan: The Shaping of Daimyo Culture, 1185–1868* (1988). WATANABE AKIYOSHI (AKIYOSHI WATANABE), KANAZAWA HIROSHI (HIROSHI

KANAZAWA), and PAUL VARLEY (H. PAUL VARLEY), *Of Water and Ink* (1986), is a thorough study of the ink monochrome painting style of this period.

Medieval ceramic history is discussed in LOUISE ALLISON CORT, *Shigaraki: Potter's Valley* (1979); JOHANNA BECKER, *Karatsu Ware* (1986); and TSUGIO MIKAMI, *The Art of Japanese Ceramics* (1972; originally published in Japanese, 1968).

The artistically explosive final years of the 16th century are treated in METROPOLITAN MUSEUM OF ART (NEW YORK, N.Y.) and JAPAN, BUNKACHŌ, *Momoyama: Japanese Art in the Age of Grandeur* (1975); TSUNEO TAKEDA, *Kano Eitoku* (1977; originally published in Japanese, 1974); and HAYASHIYA SEIZŌ (SEIZŌ HAYASHIYA), *Chanoyu: Japanese Tea Ceremony* (1979). MOTOO HINAGO, *Japanese Castles*, trans. from Japanese and adapted by WILLIAM H. COALDRAKE (1986); FUMIO HASHIMOTO (ed.), *Architecture in the Shoin Style*, trans. and adapted by H. MACK HORTON (1981; originally published in Japanese, 1972); and MITCHELL BRING and JOSSE WAYEMBERGH, *Japanese Gardens: Design and Meaning* (1981), discuss important innovations in spatial aesthetics.

A broad overview of the artistically eclectic Edo period is found in WILLIAM WATSON (ed.), *The Great Japan Exhibition: Art of the Edo Period, 1600–1868* (1981). The emergence of a distinctive decorative tradition is treated in CAROLYN WHEELWRIGHT (ed.), *Word in Flower: The Visualization of Classical Literature in Seventeenth-Century Japan* (1989); and HOWARD A. LINK, *Exquisite Visions: Rimpa Paintings from Japan* (1980). Chinese-inspired literati painting is summarized in JAMES CAHILL, *Scholar Painters of Japan* (1972); and CALVIN L. FRENCH, *The Poet-Painters: Buson and His Followers* (1974). Other styles of painting are discussed in ST. LOUIS ART MUSEUM and SEATTLE ART MUSEUM, *Ōkyo and the Maruyama-Shijō School of Japanese Painting* (1980); and STEPHEN ADDISS, *The Art of Zen* (1989). MIYAJIMA SHIN'ICHI (SHIN'ICHI MIYAJIMA) and SATŌ YASUHIRO (YASUHIRO SATŌ), *Japanese Ink Painting*, ed. by GEORGE KUWAYAMA (1985), is especially informative on Edo-period "eccentric" painters.

RICHARD LANE, *Images from the Floating World: The Japanese Print* (1978, reissued 1982), combines general essays with a detailed, illustrated dictionary. ROGER S. KEYES, *Japanese Woodblock Prints: A Catalogue of the Mary A. Ainsworth Collection* (1984), provides informative thematic essays interpreting a specific collection. JACK HILLIER, *The Art of the Japanese Book*, 2 vol. (1987), is a comprehensive resource.

Art of the Meiji period is introduced by FREDERICK BAEKELAND and MARTIE W. YOUNG, *Imperial Japan: The Art of the Meiji Era, 1868–1912* (1980). Other works of note include HENRY D. SMITH II, *Kiyochika: Artist of Meiji Japan* (1988); and JULIA MEECH-PEKARIK, *The World of the Meiji Print: Impressions of a New Civilization* (1986). (J.T.U.)

Music. *China:* Western-language sources are listed in FREDRIC LIEBERMAN, *Chinese Music: An Annotated Bibliography*, 2nd, rev. and enlarged ed. (1979). Also of interest are RULAN CHAO PIAN, *Sonq Dynasty Musical Sources and Their Interpretation* (1967); R.H. VAN GULIK, *The Lore of the Chinese Lute*, new ed., rev. (1969); LAURENCE PICKEN (ed.), *Music from the Tang Court*, 5 vol. (1981–90); KENNETH J. DEWOSKIN, *A Song for One or Two: Music and the Concept of Art in Early China* (1982); LIANG MINGYUE (MING-YÜEN LIANG), *Music of the Billion: An Introduction to Chinese Musical Culture* (1985); BELL YUNG, *Cantonese Opera* (1989); COLIN MACKERRAS, *The Rise of the Peking Opera, 1770–1870* (1972), and *The Performing Arts in Contemporary China* (1981); and RICHARD CURT KRAUS, *Pianos and Politics in China: Middle-Class Ambitions and the Struggle over Western Music* (1989).

Korea: The major sources for Korean music study are in Asian languages; some are available in BANG-SONG SONG (trans.), *Source Readings in Korean Music* (1980). General studies are LEE HYE-KU (HYE-GU YI), *Essays on Traditional Korean Music*, trans. and ed. by ROBERT C. PROVINE (1981); and LEE HYE-KU (HYE-GU YI) (compiler and ed.), *Korean Musical Instruments*, trans. by ALAN C. HEYMAN (1982). Older works may be found by consulting BANG-SONG SONG, *An Annotated Bibliography of Korean Music* (1971).

Japan: General introductions are FRANCIS PIGGOTT, *The Music and Musical Instruments of Japan*, 2nd ed. (1909, reprinted 1971); and WILLIAM P. MALM, *Japanese Music and Musical Instruments* (1959, reissued 1990). Special studies are ROBERT GARFIAS, *Music of a Thousand Autumns: The Tōgaku Style of Japanese Court Music* (1975); WILLEM ADRIAANSZ, *The Kumiuta and Danmono Traditions of Japanese Koto Music* (1973); BONNIE C. WADE, *Tegotomono: Music for the Japanese Koto* (1976); WILLIAM P. MALM, *Nagauta: The Heart of Kabuki Music* (1963, reprinted 1973), and *Six Hidden Views of Japanese Music* (1986); and C. ANDREW GERSTLE, KIYOSHI INOBE, and WILLIAM P. MALM, *Theater as Music* (1990), an examination of a bunraku play. (W.P.M.)

Dance and theatre. *General works:* JAMES R. BRANDON (ed.), *The Cambridge Guide to Asian Theatre* (1993); MARTIN BANHAM (ed.), *The Cambridge Guide to World Theatre* (1988); JOEL TRAPIDO (ed.), *An International Dictionary of Theatre Language* (1985); and *Asian Theatre Journal* (semiannual), contain useful entries on East Asian Theatre.

China: Critical studies include A.C. SCOTT, *The Classical Theatre of China* (1957, reprinted 1978), a standard work; the excellent history of the Peking opera by Mackerras cited above in the section on music; LIU WU-CHI (WU-CHI LIU), *An Introduction to Chinese Literature* (1966, reissued 1990), an analysis of individual playwrights and their works; J.I. CRUMP, *Chinese Theater in the Days of Kublai Khan* (1980), a study of Yüan drama; WILT IDEMA and STEPHEN H. WEST, *Chinese Theatre, 1100–1450: A Source Book* (1982), translations of theatre documents; COLIN MACKERRAS (ed.), *Chinese Theater: From Its Origins to the Present Day* (1983), a comprehensive survey; ROBERTA HELMER STALBERG, *China's Puppets* (1984), a well-illustrated introduction; and TAO-CHING HSÜ, *The Chinese Conception of the Theatre* (1985), a compilation of Chinese historical sources.

Korea: Studies of various Korean performing arts are CH'OE SANG-SU (SANG-SU CH'OE), *A Study of the Korean Puppet Play* (1961), a detailed study with illustrations and translations of two play texts; HALLA PAI HUHM, *Kut: Korean Shamanist Rituals* (1980); and KOREAN NATIONAL COMMISSION FOR UNESCO (ed.), *Korean Dance, Theater, and Cinema* (1983).

Japan: Overviews of Japanese performing arts are BENITO ORTOLANI, *The Japanese Theatre* (1990); KAWATAKE TOSHIO (TOSHIO KAWATAKE), *Japan on Stage: Japanese Concepts of Beauty as Shown in the Traditional Theatre* (1990; originally published in Japanese, 1982), on the appeal of traditional performance to Japanese and non-Japanese audiences; JACOB RAZ, *Audience and Actors: A Study of Their Interaction in the Japanese Traditional Theatre* (1983); and YOSHINOBU INOURA and TOSHIO KAWATAKE, *A History of Japanese Theater*, 2 vol. (1971, reissued in 1 vol. as *The Traditional Theater of Japan*, 1981).

MASATARO TOGI, *Gagaku: Court Music and Dance* (1971), provides an overview of this art form's various styles and genres.

Studies of the history and interpretation of nō and *kyōgen* theatre are found in MONICA BETHE and KAREN BRAZELL, *Nō as Performance* (1978); DONALD KEENE and KANEKO HIROSHI (HIROSHI KANEKO), *Nō: The Classical Theatre of Japan*, rev. ed. (1973); KUNIO KOMPARU (KUNIO KONPARU), *The Noh Theater: Principles and Perspectives* (1983; originally published in Japanese, 1980); THOMAS BLENMAN HARE, *Zeami's Style: The Noh Plays of Zeami Motokiyo* (1986); REBECCA TEELE (compiler), *Nō/Kyōgen Masks and Performance* (1984), essays by Japanese artists and Western scholars; and J. THOMAS RIMER and YAMAZAKI MASAKAZU (trans.), *On the Art of the Nō Drama: The Major Treatises of Zeami* (1984).

Historical and interpretive examinations of kabuki include EARLE ERNST, *The Kabuki Theatre* (1956, reissued 1974); MASAKATSU GUNJI and CHIAKI YOSHIDA, *Kabuki*, trans. from Japanese (1969); MASAKATSU GUNJI, *Buyo: The Classical Dance*, trans. from Japanese (1970); and SAMUEL L. LEITER, *Kabuki Encyclopedia* (1979).

Works treating the history and interpretation of bunraku include BARBARA ADACHI, *The Voices and Hands of Bunraku* (1978); DONALD KEENE and KANEKO HIROSHI (HIROSHI KANEKO), *Bunraku: The Art of the Japanese Puppet Theatre*, rev. ed. (1973); C.J. DUNN, *The Early Japanese Puppet Drama* (1966); and C. ANDREW GERSTLE, *Circles of Fantasy: Convention in the Plays of Chikamatsu* (1986).

Modern theatre history and interpretation are explored in ETHAN HOFFMAN *et al.*, *Butoh: Dance of the Dark Soul* (1987); SUSAN BLAKELEY KLEIN, *Ankoku Butō: The Premodern and Postmodern Influences on the Dance of Utter Darkness* (1988); TOYOTAKE KOMIYA, *Japanese Music and Drama in the Meiji Era*, trans. from Japanese (1956, reissued 1969); J. THOMAS RIMER, *Toward a Modern Japanese Theatre* (1974); and TADASHI SUZUKI, *The Way of Acting* (1986; originally published in Japanese, 1984). (J.R.B.)

Eastern Africa

Eastern Africa is a part of sub-Saharan Africa that comprises two traditionally recognized regions: East Africa, made up of Kenya, Tanzania, and Uganda; and the Horn of Africa, made up of Somalia, Djibouti, Eritrea, and Ethiopia. The Horn of Africa, containing such diverse areas as the Ethiopian highlands, the Ogaden desert, and the Eritrean and Somalian coasts, is home to the Amhara, Tigray, Oromo, and Somali peoples, among others. Washed by the Red Sea, the Gulf of Aden, and the Indian Ocean, this region has long been in contact with the Arabian Peninsula and southwest Asia. Islām and Christianity are of ancient standing here, and the people speak Hamito-Semitic tongues related to the languages of North Africa and the Middle East. East Africa, too, has a long history of contact with Arabia, particularly through the island of Zanzibar and the ancient ports of the Swahili coast, but it was through the Bantu kingdoms near Lake Victoria and through the farming and cattle-raising cultures of the Kenyan highlands that this region, early on, showed a much closer affinity with sub-Saharan Africa.

Both regions went through periods of conquest and colonization by European powers, the Horn being controlled by Italy, France, and Great Britain and the East African lands becoming protectorates of Britain and Germany. It is to this era, which finally came to an end in 1977 with the independence of Djibouti, that the seven countries discussed in this article owe their present boundaries.

This article begins with a description of the geography and economy of all of eastern Africa; it then proceeds with sections on the cultures and histories of East Africa and the Horn of Africa. Following these regional treatments are sections on the geography and the history of each country. For more detailed geographic information, see AFRICA. For treatments of regions related to eastern Africa, see CENTRAL AFRICA; NORTH AFRICA; SUDAN, THE; EGYPT; and ARABIA. For artistic expressions, see AFRICAN ARTS. (Ed.)

The article is divided into the following sections:

THE REGION

The land

RELIEF

The physical basis of eastern Africa is a platform of ancient resistant rocks that has been contorted and inset with granites but worn down by prolonged erosion to extensive plains. Its present outlines derive from the splitting apart of the ancient supercontinent of Gondwanaland, of which Africa forms a part. In eastern Africa the straight coastlines of Eritrea and northern Somalia were created by the drifting away of the Arabian Peninsula, which opened up the Red Sea and the Gulf of Aden, and the smooth shorelines and deep waters along the eastern coast mark the departure of India and Madagascar. Too rigid for folding to take place, the platform on which eastern Africa rests has been buckled by subterranean forces into broad basin-and-swell structures hundreds of miles across. Associated with these tensional forces, extensive faulting has raised and lowered vast blocks of land, leaving prominent escarpments between them, and extruded lavas have formed elevated plateaus and have spread across the plains as well as forming numerous volcanoes. The most striking of these features is the East African Rift System, of which the main branch, known as the Eastern Rift Valley or Great Rift Valley, extends from the junction of the Red Sea and the Gulf of Aden, crosses the summit of two centres of uplift in Ethiopia and Kenya, and enters northern Tanzania, where it largely disappears only to reappear in the south of that country in the Lake Nyasa trough (Lake Nyasa is also known as Lake Malawi). The Western Rift Valley curves along the western border of Uganda and Tanzania, where it is marked by Lakes Albert and Tanganyika, and is aligned through the Lake Rukwa trough with the head of Lake Nyasa. Although not entirely continuous or uniform, the rift valleys are typically some 35 miles (60 kilometres) across and, where they cut through highland, may have inward-facing scarps of 1,500 to 3,000 feet (500 to 1,000 metres) in elevation. The two most striking highlands, found in Ethiopia and Kenya, are formed of lava flows piled on top of areas of uplift on either side of the Great Rift.

The East African Rift System

These fundamental geologic factors are reflected in the major physiographic regions of eastern Africa. The Ethiopian highlands, for example, are formed from lava flows that have created extensive plateaus at elevations of 6,500 to 10,000 feet. The plateaus are separated by deep, river-worn gorges and are marked by isolated summits rising to over 12,000 feet. The northern end of the Rift Valley

is a region of confused relief, characterized by downfaulting to below sea level in the Kobar Sink and by active volcanoes and hot mineral springs. The Kenyan highlands are constructed by lava flows piled upon a broad, uplifted dome that is dissected by the Great Rift Valley. There the shoulders of the Rift highlands rise to nearly 12,000 feet, but of greater height are giant extinct volcanoes on the outer edge of the volcanic province—Mounts Elgon and Kenya and Kilimanjaro, the latter, at 19,340 feet (5,895 metres), the highest mountain in Africa. In southern Tanzania the continuation of the Great Rift Valley is bordered by the Southern and Nyasa highlands, which overlook Lake Nyasa; and the Western Rift is bordered by the Ufipa Plateau, which lies above Lake Rukwa. In Uganda the Western Rift Valley is flanked by high ground in Kigezi and Karagwe and by the upfaulted block of the Ruwenzori Range.

Between the arms of the two Rift valleys lies the Central Plateau, an extensive, eroded surface comprising most of Uganda and western Tanzania. Lying mostly at 3,000 to 4,500 feet, it is a major example of a peneplain created by long periods of erosion but bearing isolated ridges and hill masses of more resistant material called inselbergs. East of the Great Rift, the surface is further diversified by faulting and then gives way to a coastal zone of sedimentary stratified rocks; this creates a gently varied relief of plateaus, escarpments, and riverine plains. In the Tana River basin of eastern Kenya and in most of Somalia, the original land surface has sunk thousands of feet below sea level; this has been covered by more recent sediments, which have resulted in extensive and very complete plains.

DRAINAGE

Inland basins

Rivers and lakes. The Great Rift Valley is the centre of a remarkable line of inland drainage basins; radiating outward from its bordering highlands, other waters drain to the Indian and Atlantic oceans and to the Mediterranean Sea. The area of inland drainage extends from Lake Abaya in southern Ethiopia through Lake Rudolf (or Lake Turkana) in Kenya to the strongly alkaline lakes of Natron, Manyara, and Eyasi in northern Tanzania. Lake Rukwa is the centre of a separate basin of inland drainage. There is little drainage in the arid coastlands of the Red Sea and the Gulf of Aden, but the strongly seasonal Shebele (or Shabeelle) and Jubba rivers manage to carry runoff from the summer rains of Ethiopia across Somalia to the Indian Ocean. The Tana and Athi-Galana systems from the Kenyan highlands are more reliable, as are those of eastern Tanzania, notably the extensive Rufiji–Kilombero–Great Ruaha system.

The Nile has its headwaters in the eastern African highlands and plateaus, forcing Egypt to maintain an interest in dams built in Ethiopia and Uganda. (Actually, it is the Blue Nile, or Abay, River and the Atbara and Sobat rivers that bring seasonal floods to The Sudan and Egypt, while the more regular flow of the White Nile is derived from Lake Victoria.) Another great river, the Congo, receives contributions from the southern portion of the Central Plateau through the Malagarasi River, which debouches into Lake Tanganyika. This lake is some 400 miles long but has an average width of only 30 miles. Also, although it has a surface elevation of some 2,500 feet, its bottom reaches to about 2,200 feet below sea level.

Groundwater. The seasonal nature and general scarcity of rainfall over much of eastern Africa makes groundwater supplies especially significant. The volcanic strata of the Rift highlands are particularly useful in storing water, releasing it into springs and rivers or providing good well sites. But water does not so easily penetrate the hard rocks of the underlying platform, where groundwater tends to be limited to small and localized pockets. The layered sediments of Somalia and the coastal plains absorb rainfall, but it is liable to be lost to great depths and, if reached by boreholes, may prove saline.

SOILS

Soils vary greatly, but a broad pattern can be discerned in relation to climate (especially rainfall), to drainage, and to parent material.

Soils of the drier regions. The arid and semiarid zones of the Eritrean coast, Somalia, northern Kenya, and the Ogaden region of Ethiopia are mostly covered with shallow soils, often stony and little-weathered. They include almost bare lavas near the Rift Valley and calcareous clay loams over sedimentary limestones to the east. Residual gypsum is common in northern Somalia. Less arid areas are characterized by intermediate or dryland soils that are more thoroughly, but not deeply, weathered; these reddish soils are rich in iron, which is often found as granules on the surface or in a buried layer, and they are of average agricultural value, being useful under irrigation. Less fertile are the old and greatly weathered soils of much of Tanzania, which form a recurrent topographic sequence, or catena, according to whether they are located on a level plain, on a gentle slope, or in a broad, shallow drainage channel at the foot of a slope. The upper plateau soils tend to be deeply weathered and leached sandy loams. On the slopes, soil movement exposes less weathered material, and fertility and drainage are more favourable for agriculture. The drainage channels are frequently waterlogged, giving rise to mottled sandy loams or to a black clay that can be richer in minerals and nutrients but difficult to cultivate. Over extensive areas of the plateaus, the residual iron content of the soil is enough to form a crust of ironstone or laterite.

Infertile soils

Soils of the wetter regions. Highland soils form a distinctive category because of the climate but also because so many of them are derived from volcanic material. The bright red, rich clay loams of Kenya and similar volcanic uplands result from deep weathering under ample rainfall, yielding a highly fertile basis for agriculture. At cooler elevations above about 6,500 feet, soil colour changes to a deep brown, but fertility, as on the Ethiopian Plateau, remains high. Poorly drained lava surfaces can weather into plains of black cracking clay (also called vertisol or "black cotton" soil), a poor foundation for buildings or roadworks. Soil erosion is particularly serious on steep slopes of the highlands of Eritrea, Ethiopia, and Kenya, where clearance of the prized soils for cultivation leads to silt-laden rivers, gullied landscapes, and loss of topsoil.

CLIMATE

Straddling the Equator from latitudes 18° N to 18° S, eastern Africa's climate is dominated by its tropical location and by a great range of elevation. Average temperatures are reduced by the high average elevation, but only on the highest mountains is the temperature low enough to restrict the growth of vegetation. It is the amount and seasonal duration of rainfall that distinguishes most climatic regions. As the sun moves into either the northern or southern tropic, so converging air flows, which are uplifted as they meet at a zone of low pressure called the intertropical convergence zone, bring intense summer rains; these are followed by a winter dry season as the sun shifts to the other tropic. Thus, northern Uganda and central and southern Tanzania receive 20 to 48 inches (500 to 1,200 millimetres) of rainfall in a five- to eight-month season. Around Lake Victoria on the Equator, more continuous rains follow from two seasons of overhead sun and from the local effects of the vast surface of the lake. Arid Somalia and northeastern Kenya are anomalous in these latitudes, with rainfall less than 10 inches per year. There, in the northern summer, airflow diverges toward the low pressure of the Indian Ocean monsoon system, resulting in a gently subsiding atmosphere rather than the uplift needed to generate precipitation. In winter a contrary outflow from Southwest Asia brings little moisture, but one along the Red Sea brings winter rain to dry coastal Eritrea.

Effects of elevation on climate

The major highlands are sufficiently extensive to form a major exception to these patterns. Even at the Equator, a reduction in temperature at elevations above 5,400 feet creates climates outside the tropical category, with important implications for agricultural ecology and health. The highest mountain summits rate as alpine, with glaciers present on Kilimanjaro and other peaks. Even lower relief features are sufficient to generate locally enhanced precipitation, and coastal locations in Tanzania and southern Kenya also experience locally high rainfalls.

Cities and towns

Physical features and points of interest

With rainfall so dependent on airflow, fluctuations in the large-scale dynamic systems can move the boundary of adequate moisture hundreds of miles, bringing drought to such areas as highland Eritrea, Tigray in Ethiopia, Machakos in Kenya, and Dodoma in Tanzania.

PLANT AND ANIMAL LIFE

Plants. Vegetation types mirror the rainfall zones, starting with scanty plant cover in the arid and semiarid areas, where infrequent succulents and stunted thornbushes survive the dry seasons and where the brief periods of rain bring short-lived ephemeral herbs and annual grasses. In more moist areas, with seasonal rainfall over 12 inches but with a pronounced dry season, the vegetation, often termed savanna, may be divided into three major physiognomic types: bushland, woodland, and wooded grassland. Bushland, characterizing the drier areas, forms a cover of small trees branching from the base with little grass between. Where this cover is dense, impenetrable thickets may be formed. Woodland is a mantle of deciduous trees whose crowns more or less touch to form a light but almost continuous canopy over a layer of grasses, herbs, and small shrubs. Its greatest extent is over the plateau of central and southern Tanzania, where rainfall totals are 32 to 48 inches per year but where there is a severe dry season of up to six months. Wooded grassland is an open mixture of trees and shrubs standing among a good growth of grass but not forming a canopy over it. In such areas the dry season seldom lasts more than three months, and this type of vegetation may actually be derived from forest cleared by human activities.

Escarpments of the Great Rift Valley rising above the plain north of Samburu Game Preserve, central Kenya. Beisa oryx graze in the foreground.

True forest in areas of low and middle elevation is not common in eastern Africa; where it formerly existed, it has in many places been cleared, as in southern Uganda and along parts of the Kenyan and Tanzanian coasts. Better preserved than these are the montane forests of the Ethiopian and Kenyan highlands. At altitudes above the timberline are heather and moorlands of Afro-Alpine vegetation.

Natural grasslands are rare and are usually caused by special circumstances, such as a high water table or cracking clays, which are disruptive to the roots of larger plants. Other vegetation types not primarily related to climate are freshwater papyrus swamps, which are locally important in southern Uganda, and mangrove forests. Modification by human activity includes deforestation, but there is also a less conspicuous diminution of plant cover and degradation of the savanna areas.

Animals. Animal life also has diminished in response to human pressures, but East Africa in particular remains justly famous for its wildlife, which includes spectacular assemblages of big game. It seems likely that these survived into the 20th century because of a low human population; also, the traditional pastoral cultures of East Africa were tolerant of the competition of wild herbivores, each tending to have its own preferred habitat. The Serengeti Plain of Tanzania still supports large migratory herds of zebra, wildebeest, antelope, and gazelle as well as the lions, cheetahs, and wild dogs that prey on them. Elephants and rhinoceroses favour more wooded areas, and in the forests are buffaloes, bushbucks, rare chimpanzees, and leopards. This pattern, too, has been affected by the spread of human settlement, which has forced animals into environments less able to support them. For example, the extension of agriculture into the wooded grasslands has confined the elephant to drier bushlands, where its browsing causes more havoc. Such disruption has been countered by restrictions on hunting and by the creation of nature reserves and national parks, of which the most famous are Serengeti in Tanzania, Amboseli and Tsavo in Kenya, and Murchison Falls (Kabalega) and Queen Elizabeth (Ruwenzori) in Uganda.

Wildlife of East Africa

Birdlife is abundant, large species including the ostrich of the plains and the flamingo and pelican of the Rift Valley lakes.

An important factor that has the effect of neutralizing human pressures and keeping land available for wildlife is infestation with the tsetse fly, which covers more than 40 percent of Kenya, Uganda, and Tanzania. Other significant insect pests include the locust, malaria-carrying mosquitoes, and the *Simulium* fly, the carrier of onchocerciasis, or river blindness.

The economy

The economies of the eastern African countries are closely related to their natural resources. The great majority of the population is directly dependent upon agriculture or pastoralism for its livelihood, and most exports are of primary agricultural products. A substantial portion of agriculture is on the subsistence level—that is, the raising of foodstuffs necessary for maintaining a livelihood, with no planned surplus left over for trade.

AGRICULTURE

Intensive cultivation. Rainfall is the dominant influence on agricultural output and, hence, on the densities of population. This basic resource varies greatly among the countries of eastern Africa. Without irrigation, arable agriculture requires a reliable annual rainfall of over 30 inches (750 millimetres). In four years out of five, this total may be expected by 78 percent of Uganda and 51 percent of Tanzania but only by 15 percent of Kenya. (The proportion of Somalia that receives this total is negligible, and in Ethiopia the range of elevations makes such totals not significant.) A large area of high-intensity agriculture is shared by the three East African countries in the Lake Victoria basin, especially in an arc from western Kenya through Buganda to Bukoba in Tanzania. Food crops here include the banana, sweet potato, taro, and yam, with Robusta coffee and cotton important cash crops. Along the East African coast, between Malindi and Dar es Salaam and including Zanzibar and Pemba, is another closely settled zone with an economy and culture enriched by a thousand years of trading with Arabia, the Persian Gulf, and the Indian subcontinent.

Highland agriculture

Other intensively cultivated areas are in the uplands and mountains, where precipitation, increased by the raised landforms, is made more available for plant growth because the cooler temperatures reduce evaporation. In many cases, as along the Great Rift Valley, the highlands are of volcanic origin, with weathered lava forming the basis for fertile, easily worked, and moisture-retentive red loams. In Kenya, Tanzania, and Uganda, cultivation has spread upward in such highlands with the introduction of temperate crops (in part furthered by European settlers), including especially the Andean, or Irish, potato, cruciferous vegetables of the genus *Brassica*, temperate species of peas and beans, and wheat and barley. The lower slopes are suited to Arabica coffee and the higher ones to tea and pyrethrum. This ascending wave of cultivation has pushed back the boundaries of the montane forests, which are now usually protected in forest reserves or national parks.

The presence of distinct agricultural zones at different elevations is most marked in Ethiopia, where the distinctive "false banana," or ensete, is grown at medium elevations in the forest belt of the south, Mediterranean fruits and vines are grown at higher elevations, and barley, wheat, and the indigenous cereal teff are grown in plowed fields on the high plateau.

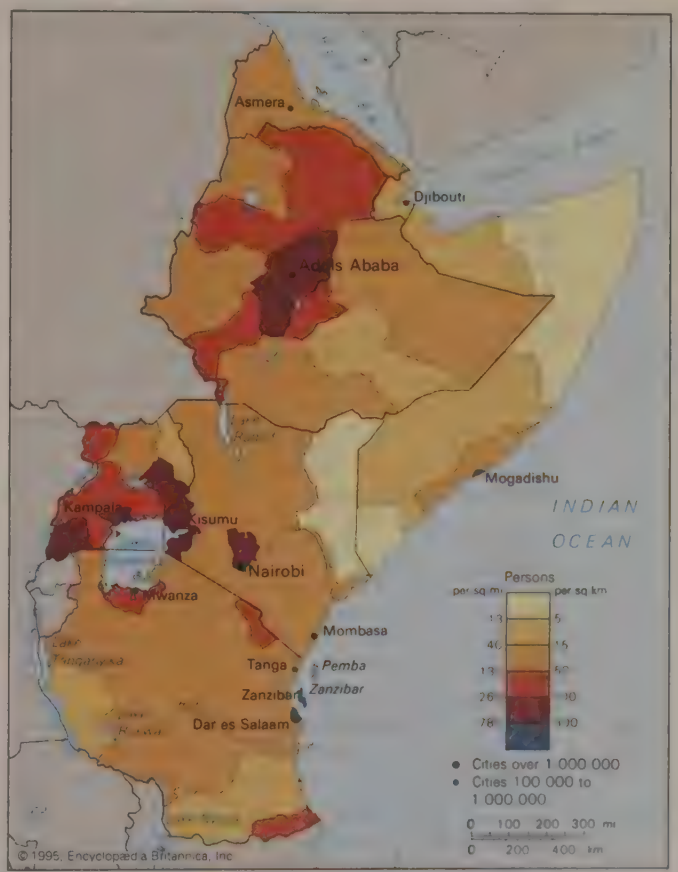
Cultivation in more arid regions. Regions with a lower annual rainfall or a pronounced dry season can only support the cultivation of less demanding, more drought-resistant crops such as sorghum, millet, and cassava. Commercial crops here include cotton and sisal. Where cattle can be kept, they improve the farming system, but, with huge areas infested by the tsetse fly, shifting agriculture is most prevalent. The agricultural problem in the drier regions is not so much a low annual rainfall as it is a long dry season, often lasting five to seven months. Another problem here is low soil fertility. Some fertility can be returned to the soil by slash-and-burn clearing and by a rotation of crops, but even this modest improvement is so quickly reduced that after a few years' cultivation the land must be allowed to return to bush fallow, preferably for 20 years or more. During this time the farmer works a sequence of clearings, which requires that he move his homestead or waste energy in long walks to his plots. With low population densities, this system provides a sustainable livelihood and a good return on the labour involved, but the scattered homesteads and their periodic abandonment make difficult the organization of modern marketing, transport and communication, and welfare services. On the other hand, greater population densities would lead to a clearing of the bush in which the tsetse flies breed, but the land so cleared would be unable to support the larger population.

Areas of typically marginal rainfall (*e.g.*, 20 to 30 inches per year) rely on a mixture of cultivation and livestock herding. In some years, which may be a majority, there is sufficient rainfall to bring a satisfactory harvest. Unfortunately, these years of agricultural plenty attract immigrants from overpopulated districts, who increase the scale of disaster when drought returns. Also, increased cultivation reduces plant cover and accelerates erosion, which further aggravates the situation. In this way, increased population intensifies the consequences of a normal climatic variation, leading in turn to an increased perception of drought and famine.

Recurring drought and famine

Livestock raising. Over large areas of eastern Africa, rainfall is inadequate for crop cultivation. This applies to the whole of Somalia and to some 70 percent of Kenya, which receive less than 20 inches in four years out of five. In areas such as these, the only feasible basis for land use is pastoralism. In the driest areas along the Red Sea coast, the whole of Somalia, and northeastern Kenya, the principal animal is the Arabian camel; elsewhere, cattle are dominant, usually in association with herds of sheep and goats and a few donkeys. These animals are multipurpose bases of livelihood, providing meat, milk, blood, hides, wool or hair, and transport. Since they are dependent upon grazing and browsing, they must be kept on the move to follow seasonal and other variations in rainfall, upon which the availability of vegetation and water depend. This nomadic way of life limits the accumulation of goods and chattels as well as the provision of such welfare services as schools and hospitals. The inoculation of livestock against disease and the construction of boreholes and reservoirs have enabled the people to increase the size of their herds, but this has led to overgrazing, with a consequent degradation of the rangeland and increased mortality in drought years. The problem here is that ownership is vested in the animals rather than the land, which is the primary resource. Therefore, it is in no one's interests to conserve grazing land, because it will only be used by someone else's herd. Also, the pastoralist is aware that experimental conservation could wipe out his herd and leave him helpless in this harsh environment. Individual or group ranches and systems of licensing have been set up to solve this quandary, but these conflict with cultural traditions and have not been very successful.

Irrigation. The irrigation of arid areas is limited by the amount of water that can be brought in from outside the



Population density of eastern Africa.

region, but not much of even this limited potential is utilized. For example, 70 percent of Kenya is cultivable only by irrigation, but only 3 percent receives more than 50 inches of rain, the minimal amount from which any considerable runoff can be expected. Only the Tana and the Athi–Galana river systems succeed in reaching the sea from the highlands, and irrigation schemes here are small. Developments in Somalia and in the Ogaden region of Ethiopia are effectively confined to the Jubba and Shebele rivers, which drain the eastern highlands and are used to grow bananas for export as well as cotton and food crops. In Ethiopia the waters of the Awash River are used as they descend from the highlands onto the floor of the Rift Valley; sugar and cotton are the major crops.

Irrigation in less arid zones

Irrigation is more promising in the less arid zones, where it can be used during the dry season or as a supplement to even out natural fluctuations in precipitation. This is done on sugar plantations in Uganda and on coffee estates in Kenya and Tanzania. Studies suggest that, if the floods of the rainy season on the Ruaha–Rufiji system of Tanzania were controlled, ample water would be available for irrigation in the dry season—as has already been demonstrated in small schemes in the Kilombero valley.

FORESTRY

The role of forests as a natural source of timber is confined by their small original extent and by deforestation. Forestry policies have been as concerned with the protection of watersheds as they have with production. Exports of natural hardwoods are very limited, although Uganda and Ethiopia can supply a modest domestic market. Local demands for softwoods are largely met by plantations of species of cypress (*Cupressus lusitanica* and *C. macrocarpa*) and pine (*Pinus radiata* and *P. patula*) derived from Central America. Black wattle (*Acacia mollissima*), introduced from Australia, is widely grown for firewood, and its spread has been greatly encouraged by being grown as a crop for tannin bark. The most widespread introduction from Australia, however, has been the eucalyptus, which, under eastern African conditions, grows very rapidly. Almost universally grown for firewood and poles, eucalyptus trees are a conspicuous part of the landscape, especially in upland Ethiopia.

FISHING

The lakes and rivers of eastern Africa are a productive natural resource. Lake Victoria and the lakes of the Rift valleys support fishing communities whose more distant markets, formerly supplied with sun-dried or smoked fish, are now being reached on a growing scale by the frozen product. Management of fish stocks has presented difficulties where lakes are bordered by more than one country, and the controversial introduction of the Nile perch into Lake Victoria has, since the 1980s, altered the balance of species in that body.

Inshore fisheries along the coast suffer from a generally narrow coastal shelf and a poor nutrient supply, except for some upwelling of deeper waters off the Somali coast during the northeast monsoon. The more remote oceanic waters are fished by foreign boats for tuna and other large fish. Game fishing for marlin, sailfish, and the like is a part of the tourist industry.

RESOURCES

Minerals. Mineral resources have so far proved disappointing. The lavas that blanket so much of Ethiopia and Kenya provide little except building stone, although the hot springs associated with volcanism have formed alkaline deposits that can be mined for soda ash and similar chemicals. The only large-scale extraction of soda ash is at Lake Magadi in Kenya.

Scarcity of commercially viable deposits

The ancient crystalline rocks of the African platform are rich in minerals that, having separated out through igneous or metamorphic processes into excellent geologic specimens, have a retail value for tourism, but there are few large, commercially viable deposits. Scattered gold finds have attracted mining, but only some of them have persisted for any length of time. Part of the most productive auriferous formation, exposed and worked in western Kenya and in Tanzania's West Lake region, lies beneath Lake Victoria. Lead and copper are among other minerals that have been mined in the past, but the most important continuing production has proved to be diamonds from one of the many Kimberlite pipes at Mwadui in Tanzania. A considerable deposit of iron ore has been proven to exist in southern Tanzania, but technical problems and difficulties of location and marketing have hindered development.

Also in southern Tanzania are deposits of coal. Exploration for oil and gas in the Red Sea region, the Tana River basin, and along the coast and offshore islands of the Indian Ocean have shown favourable indications.

Hydroelectricity. Although fossil fuels have to be imported, the majority of the region's commercial energy requirements have been met by hydroelectric power, which has considerable scope for expansion. Uganda's Owen Falls Dam provides power to both Uganda and Kenya, and it can be replicated at other sites along the Nile. Kenya has a major scheme on the upper Tana River and smaller plants and potential sites in the highlands, although the total surface flow is limited. Only a small portion of the Tanzanian potential is harnessed; the Ruaha–Rufiji system offers some good dam sites, but they would be expensive to exploit. In the high-rainfall area of the Ethiopian highlands, the great range of elevation has provided opportunities for power generation that have not fully been taken up. Only arid Somalia and Eritrea are not in a position to develop hydroelectric power.

COMMERCE AND INDUSTRY

Because the resource base for manufacturing industries is limited, the bulk of industrial exports are raw materials that are processed before shipment. Some industries based on domestic demand for such products as cement have taken enough advantage of large-scale production methods to export their products abroad. Manufacturing for local markets, over and above supplying food and beverages, takes the form of import substitution—that is, the manufacture, often from imported parts or raw materials, of goods that were once made abroad. Import-substitution industries are most successful in relatively large and affluent urban markets. In eastern Africa, this concentrates manufacturing in the capitals, which, being the largest cities and the centres of commercial functions as well as the preferred sites of international agencies, present the only areas of great demand that can sustain manufacturing activity.

Tourism

Tourism has seen different development among the East African countries (in the countries of the Horn, it is an insignificant sector of the economy). The industry is most important in Kenya, where receipts from foreign tourists are equivalent to income from a major export. Although tourism in Kenya is based on tropical beaches and on wildlife in national parks, these attractions also are found elsewhere, and contributory factors to Kenya's success are good international air connections, investment in hotels, roads, and other infrastructure, and political stability. Government policies in the other countries have been less supportive. (W.T.W.M.)

The people

EAST AFRICA

European knowledge of the peoples of the interior of East Africa began only in the second half of the 19th century, although knowledge of the coastal fringe had begun earlier, in the years after the Portuguese first made contact with Mombasa in 1498. Since the penetration of the interior most people, whether Europeans or East Africans, who have attempted to improve their comprehension of East African peoples have been struck and confused by the number of different named groups that make up the total population of the area. There are no reliable figures for the population of East Africa at the beginning of the 20th century, but, since there has been a very rapid increase since 1920, it is likely that the population in 1900 was less than 10 million. This population, however, was divided unequally among more than 160 distinct peoples—well

over this figure if a less conservative method of counting them is employed.

Identifying and classifying peoples. Although there is no complete agreement among ethnological specialists as to how a "people" or "ethnic group" is to be defined, there is substantial agreement among Africa specialists as to the vast majority of the identifiable groups in East Africa. For the purposes of this discussion, a people or ethnic group is a group of human beings who recognize their own identity and unity, have a name for themselves, and do not feel that they lose that identity in a larger grouping. Some groupings that now have the appearance of peoples, such as the Kalenjin of western Kenya, have come into being since 1960 by a conscious fusing together of older and smaller peoples. This series of fusions had not begun as early as 1900, although it is a safe speculation that most, if not all, of the peoples of that time also owed their existence in part to fusions of smaller groups at some earlier stage. For the purposes of this discussion, the year 1900 will mark the time by which East African peoples had retained practices long enough to be considered traditional and had not yet been disturbed by contact with Europeans.

Despite the fragmentation of the population into so many subdivisions, the different peoples of East Africa traditionally shared much of their cultures in common, thereby forming a smaller number of types, each type distinct in its characteristics. Africa scholars have attempted to identify and classify these types according to criteria of varying usefulness. The criteria discussed here are the following: descent, religion, language, habitat, subsistence, and political organization.

Criteria used to classify peoples

Descent. Categorizing peoples into groups according to their systems of descent and inheritance was much emphasized by writers between 1890 and 1950. Matrilineal descent—that is, formally reckoning family ties through the mother—occurred in the south (for example, among the Yao of Tanzania) and in a few pockets farther north, but most East African peoples formally reckoned descent patrilineally—that is, through the father. Bilateral descent as practiced in Europe was rare and possibly always of recent origin—that is, just before 1900.

Religion. By the late 19th century both Islām and Christianity were becoming widely known. But even before that time, most of the East African peoples took for granted a metaphysical model in which a supreme deity created and maintained the universe, and in which the spirits of dead ancestors watched over the prosperity and morals of each community and punished any offenders. In addition, the wild places were full of spirits, whose activities were unpredictable and often dangerous to humans. In order to cope with all of these mysterious powers, individuals, households, and communities consulted diviners and performed sacrifices of domestic animals. (Human sacrifices were rare.)

There were two basic variations from this model. Among the agricultural peoples living between Lakes Victoria, Albert, Edward, and Tanganyika in Uganda and northwestern Tanzania, a number of lesser gods received sacrifices along with the creator, the ancestors, and the spirits. But among the pastoral peoples of the northeast, including the Masai of southern Kenya and northern Tanzania, no attention was paid to ancestors, spirits, or gods, all devotion being directed to the creator alone.

All East African peoples were aware of the danger of witches, but, while some groups lived in terror of the next attack, others assumed that no witches lived near them.

Language. From about 1890 to 1960, East African ethnic groups were usually classified according to the affinities of the languages that they spoke. This was a very tidy method, but it gave rise to serious misapprehensions, since languages do not necessarily correlate closely with other features of culture. Indeed, language distribution, if anything, overemphasizes the diversity of East African peoples. For example, the Ganda of Uganda and the Kikuyu of Kenya speak very similar languages but are markedly distinct in traditional social organization, while the Masai resemble the Kikuyu closely in many traditional cultural details but speak an unrelated language.

The Kikuyu language belongs to the Bantu family, which covers the western, southern, and coastal areas of East Africa, while the Masai tongue belongs to the Nilotic family, which extends through the centre and north of the region. A third language group covering a large area is the Cushitic family, which includes Somali and Oromo and extends from the northeastern part of East Africa into the Horn of Africa. Apart from these, there are four or more other families, each represented by one or a few examples, but all of these four appear to have lost ground over time to the three major families.

Bantu, Nilotic, and Cushitic tongues

Habitat. A more useful way of grouping the East African peoples into types is according to their habitats, which can be summarized as follows: wet lowland, wet highland, semiarid, and arid. Wet lowland habitats are concentrated around Lake Victoria, and among the peoples found there about 1900 were the Ganda and Luo, both large in number. Wet highland habitats are less concentrated than are the lowland versions; they are strung out along the highlands of the western and eastern branches of the East African Rift System, and they occur also on a few large volcanic cones such as Kilimanjaro and Mount Kenya. The Kikuyu, living near Mount Kenya, exemplified the inhabitants of this type of habitat.

In East Africa wet country is fairly scarce, and most peoples have lived in semiarid country with a marked (but unreliable) wet season and a long dry season. The Kamba of Kenya and the Nyamwezi of Tanzania traditionally lived in different variants of the semiarid habitat, while in the arid country of northeastern Kenya lived the Somali and a few other groups. Much of this driest country was true desert, with no complete vegetation cover. The Masai, not very numerous but covering a large area, lived in a less austere version of Somali country.

Subsistence. Classification according to the four main types of habitat provides a more manageable number of peoples than the 160 named groups, but this method has the weakness of grouping together peoples that live in the same type of country and yet are marked by substantial differences in culture. Taking this complication into account, another way of classifying peoples is by their method of subsistence, that is, the physical basis of their survival. Again, four main types can be recognized among the peoples as they lived about 1900: hunters and gatherers, pastoralists, desultory cultivators, and intensive cultivators.

In 1900 only two peoples seem to have been hunting and gathering societies, divided into small bands among whom the men hunted larger wild animals while the women provided most of the food by gathering wild produce, most of it of vegetable origin. These two peoples were the Okiek of Kenya and the Hadza of Tanzania. They had no domestic animals except dogs and rarely, if ever, grew cultivated crop plants.

By contrast, pastoralists covered a much larger portion of East Africa, concentrating in the most arid areas of the north and northeast and extending through semiarid areas toward the centre of what is now Tanzania. The Masai, extending farther south than other pastoral peoples, kept goats, sheep, and cattle, with their value system revolving particularly around cattle. Most of the other pastoralists also placed an extreme value upon cattle, but, with the aridity of the country increasing toward the north and northeast, camels became more important to the survival of pastoral groups and, in the deserts of the Horn, replaced cattle as the high-prestige livestock among the Rendile and Somali. It is likely, but impossible to check, that the intense valuation of camels was derived from the Middle East, with cattle traditionally being the high-prestige livestock south of the Sahara.

Pastoralism

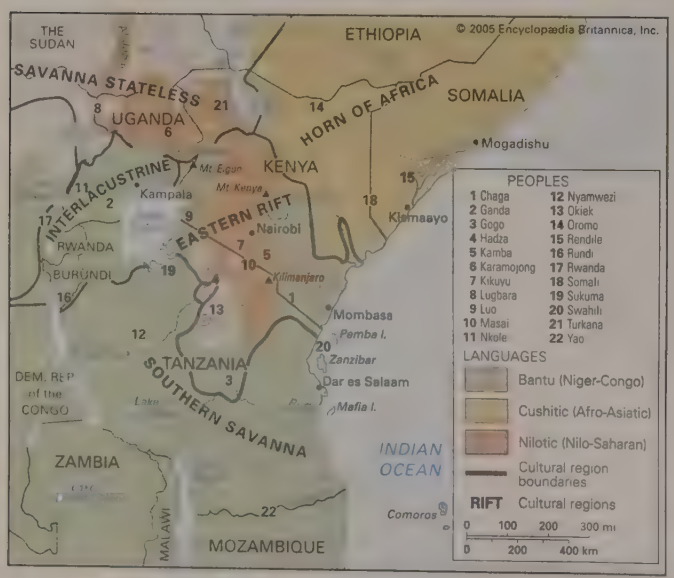
Although the term pastoralist can be used in a broad or a narrow sense, it is used here to mean peoples who depended for their survival on their herds and flocks. Among these groups, cultivation of crops was absent or ephemeral, and they relied little on hunting or gathering. However, they did rely very heavily on trading with their cultivating neighbours for an essential supply of grains and vegetables, which they did not produce themselves. In such trade, the high value of livestock and animal

products gave the pastoralists a strong bargaining position. However, they were also extremely vulnerable, because when drought or epizootics (epidemics among livestock) reduced their living capital they had no reserves on which to fall back. In such circumstances (apparently not infrequent), their main remedy was for the young men to run off somebody else's dwindling resources, and this is probably the reason for the pastoralists' reputation among their cultivating neighbours as ferocious raiders of herds and flocks. However, although the pastoral groups saw themselves as lords of creation, their distribution indicates that they lived only in areas where rain was too scarce or too unreliable to raise crops every year, if at all.

Scarce and unreliable rainfall were problems not only of the pastoralists; most of the cultivating peoples also lived with recurrent drought as a constant threat. An important buffer against the worst effects of drought was the buildup of herds and flocks, much as the pastoralists did. Then, in a dry year, the animals could be moved to water, whereas crops could not. Such was the high value that some cultivating peoples placed upon their livestock that they had much the same attitudes as pastoralists: they relied upon livestock as reserve wealth, identified themselves with their herds, and brought their livestock into their colour symbolism and songs. Examples of such peoples were the Kamba and Gogo of Kenya and Tanzania, respectively, and the Karamojong and Jie of Uganda. These peoples can conveniently be characterized as "would-be pastoralists." Their attitudes, however, did not impress the exclusive pastoralists—for instance, the Masai—who regarded their Kamba and Gogo neighbours as degraded by cultivation. Equally degraded in their eyes were those Masai who, having lost some or all of their livestock, found themselves forced to cultivate on the margins of the Masai plains, where rainfall was just adequate for an unreliable return. These Masai became, for the time at least, "would-be pastoralists."

Desultory cultivators

The desultory cultivators were peoples who lived in semi-arid country and put only a limited effort into working the soil, probably because they had a rough sense of the cost-benefit balance involved and realized that much of such effort would be lost to drought and, even in wet years, to pests such as insects and birds. There were even extra hazards associated with livestock. Over much of the northern half of East Africa, cattle-raising could be combined with cultivation. But over much of the southern half, in what is now Tanzania, the type of dry woodland often called miombo long has harboured tsetse flies, which carry infectious protozoans of the genus *Trypanosoma* that kill off cattle in these areas. Goats, sheep, and chickens could survive much better there, but in the southern half of East Africa it seems that, about 1900, most cattle were in the highlands, above the main tsetse areas.



Cultural and linguistic regions of East Africa.

Throughout East Africa, the highlands provided some of the best opportunities for intensive cultivation, because the rainfall there was relatively abundant and reliable. Similar opportunities occurred in lower areas of high rainfall, as around Lake Victoria, and on parts of the coast. An additional asset was fertile soil, since most East African, and indeed most tropical, soils are poor in plant nutrients. Soils formed locally over volcanic deposits, as in Kikuyu country, or over alluvial deposits, as in Luo country of western Kenya and north-central Tanzania, have a fertility that made possible dense populations, but only over relatively small areas. Intensive cultivation was the exception, not the rule, because the opportunities to make it work were exceptional. Where the opportunities occurred, however, cultivation repaid the hard work of tillage with hoes, making it worthwhile to hoe in great quantities of cattle dung and even to irrigate, as did the Chaga on Kilimanjaro.

Political organization. Contrasting the various modes of subsistence refines the classification of peoples based solely upon the dryness or wetness of their habitats. One further refinement, however, is necessary, and this is the contrast between those areas where the peoples were organized into states and those where they were not. The East African states were of various sizes, but all were characterized by hereditary heads of state (like European kings), by distinctions of social class, by formal administrative procedures, and, most vital of all, by procedures for collecting the taxes or tributes upon which each state's survival depended. Of the states, the largest in population were Buganda (the 19th-century kingdom of the Ganda people), Zanzibar (part of modern Tanzania), and Rwanda and Burundi.

Stateless peoples

By contrast with the states, in huge areas of East Africa the local peoples had no kings, no social classes, and no taxes. Everyone was a member of a local community but not of a larger administrative unit. The main social distinctions among these people were based on age, sex, and ability. Each local community's members conducted their own relations with other communities, and, if rival communities fought each other, the available fighting men might number from perhaps 15 to 50 on each side—whereas the kings of the largest states could put thousands of men in the field. Needless to say, local communities had difficulty resisting the might of kings. One example of such kingless and stateless peoples was the Masai.

Cultural regions. The clear and compact distribution of states and stateless societies provided a firm basis for the division of East Africa, in about 1900, into a limited number of distinct cultural regions. All the peoples of the south and west lived in states, while those of the north and northeast were stateless. None of the pastoral peoples had states, and neither did the few hunting and gathering peoples, so that the distribution of states and stateless societies largely reflected differences in the organization of the cultivating peoples. Among these, examples of both desultory and intensive cultivators were organized into states, while both types of cultivation were also found among the stateless peoples. For example, the Kikuyu had no states but were intensive cultivators, while the Chaga, who were equally intensive cultivators, did have states. Among peoples without intensive methods, the Gogo had no states—except in the west, where they adjoined the Nyamwezi, who had states and were equally unintensive in their cultivation methods.

In order to refine this scheme of cultural classification based upon the presence or absence of states, reference can be made to the custom of age-sets, and the distinctions that emerge thereby can be strengthened by further reference to the practices of circumcision and clitoridectomy. Age-sets were general throughout the northeast of East Africa, for example, among the Oromo and Masai. They were groups of males of roughly the same age who formally came of age during the same period and were for the rest of their lives ritually bound together, rather like adopted brothers, with all the other men in their set. In each area the sets formed a graded series, oldest men at the "top" until they retired and youngest men at the "bottom." Older always had authority over younger. Ini-

tiation into a set in most but not all areas was by way of circumcision, the cutting off of all or part of the foreskin of the penis. In most areas where circumcision was practiced, there also occurred "female circumcision," although there were no age-sets for women. In the female rite, the clitoris was cut out (clitoridectomy), and often the labia minora were also removed.

Five cultural regions of East Africa

The presence or absence of clitoridectomy, circumcision, age-sets, and states makes it possible to recognize five traditional cultural regions in East Africa, each of which possesses its own characteristics. These five are the Horn of Africa region, the Eastern Rift region, the Savanna Stateless region, the Interlacustrine region, and the Southern Savanna region.

The Horn of Africa. Although most of this region lies north of East Africa and is therefore discussed separately below, it does extend into the northeast part of Kenya. The Horn has closer cultural affinities with Arabia than with the four sub-Saharan regions of East Africa, owing to a long history of literacy, of large imperial states, and of Islām and Christianity—all of which are relatively new features in most of the other regions. In addition, the plow has long been an important aid to cultivation in the Horn, and the one-humped Arabian camel is an ancient domestic animal there. Most of the people of the Horn bear physical traits of the European geographic race, looking rather like dark-skinned Mediterraneans, while most people of sub-Saharan East Africa are of the African geographic race.

That part of the Horn within East Africa was inhabited, about 1900, by stateless pastoralists who kept in contact with nearby cultivating peoples in the Ethiopian highlands and in the river valleys of Somalia. Among these pastoralists, the Oromo kept cattle and camels, the Somali kept mostly camels, and both groups kept sheep and goats. The Somali were expanding at the expense of the Oromo, absorbing them culturally, so that increasingly more Oromo groups were losing their identity and becoming Somali. The Oromo had age-sets, but age-sets were maintained by only a few Somali groups in the south, where they doubtless had recent Oromo ancestors. The Somali circumcised because they were Muslims, but circumcision probably predates Islām in the Horn; certainly the non-Muslim Oromo practiced it long before 1900. Parallel to circumcision was clitoridectomy, there in a specialized form known as infibulation, in which, after the excising of the clitoris and labia minora, the opening to the girl's vagina was sewn up, leaving only a small aperture until she was married, when the vaginal opening was widened again.

The Eastern Rift. Although widespread in the Horn of Africa, infibulation did not spread to the four sub-Saharan regions. In the Eastern Rift region, however, clitoridectomy and circumcision were practiced, and male age-sets were found in all its areas except some border zones. Because age-sets, circumcision, and clitoridectomy were absent west and south of the Eastern Rift, it is tempting to speculate that these three cultural features spread southward into the region from the Horn. However, in the absence of written records before the arrival of Europeans, this theory is merely inferred from the distribution of the practices, and there is no positive evidence for it. Eastern Rift peoples had no states or kings, and they were well exemplified by the Kikuyu, the Kamba, and the Masai.

The Savanna Stateless. As its name implies, the Savanna Stateless region also lacked states, but it was set off from the Eastern Rift region by the absence of circumcision and clitoridectomy. (This region, it must be said, extended westward along the northern savanna of Africa into parts of West Africa, and there circumcision and clitoridectomy were found in places. However, in East Africa the contrast between the two regions was clear.) Age-sets did occur in the east of the Savanna Stateless region—for example, among the pastoralist Turkana and the "would-be pastoralist" Karamojong—but they were absent west of these peoples, so that the Lugbara and their neighbours in northwestern Uganda did not practice them.

The presence and absence of age-sets

The Interlacustrine and Southern Savanna. South of the savanna, the Interlacustrine peoples (those peoples living between the lakes now named Victoria, Albert, Edward, and Tanganyika) had states and kings, as did the ethnic groups of the Southern Savanna region, which covers most of western, southern, and coastal Tanzania. However, these two regions differed from each other in their traditions of kingship. Among the Interlacustrines, kings and kingdoms were linked to great ceremonial drums, more than one per state, which held the vitality of their state within them. This link was lacking in the Southern Savanna states, where a variety of locally important insignia marked off the kings from their subjects. (No African kings wore crowns.)

Another distinction between the two regions was that the Interlacustrine peoples, with few exceptions, were divided into castes of differing social prestige. In theory, but apparently not in practice, people of one caste were not allowed to marry members of another. Ranking of castes can be illustrated by the kingdom of Rwanda, where the Tutsi had higher prestige than the Hutu, and the Hutu were above the Twa. Among the Nkole peoples of western Uganda, the Hima were above the Iru. The Ganda, however, did not have castes. Southern Savanna peoples, all of them casteless, included the Nyamwezi and the Yao.

In these two regions (at least in those parts within East Africa) there was traditionally no circumcision or clitoridectomy. However, the Southern Savanna region extended westward across the continent to the Atlantic Ocean, and in the west, circumcision was practiced over a large area. Another complication, apparent by 1900, was that, as increasingly more men became Muslims, they were circumcised. The Swahili peoples of coastal East Africa had long been Muslim and had long been in contact with the Middle East, but with their penetration of the interior during the 19th century, Islām also spread and brought with it the new practice of circumcision. (J.D.K.)

THE HORN OF AFRICA

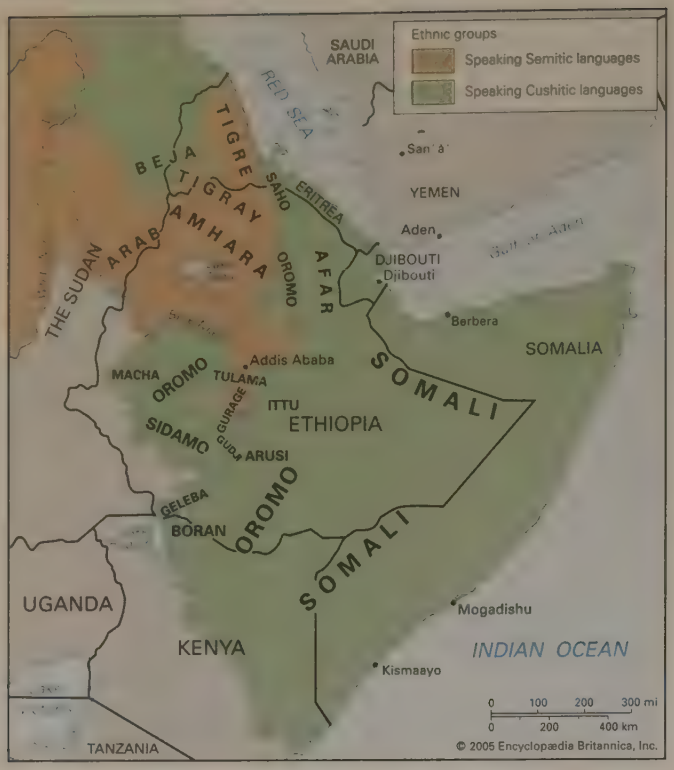
The Horn of Africa, an extension of land between the Indian Ocean and the Gulf of Aden, is occupied by Ethiopia, Eritrea, Somalia, and Djibouti, whose cultures have been linked throughout their long history.

Principal ethnic groups. Ethiopia has a history of independent sovereignty extending at least 2,000 years. Discounting the brief Italian intrusion (1935–41), it was the only traditional empire to survive the colonial partition intact. Until the mid-1970s Ethiopia was ruled by leaders drawn almost exclusively from the two dominant ethnic groups, the Semitic-speaking Tigray and Amhara. Ethiopia is thus essentially the political expression of the cultural nationalism of these two closely related peoples, who derive from a fusion of local Cushitic-speaking stock with South Arabian immigrants who settled along the Red Sea coast in the 1st millennium BC.

The Tigray and Amhara

The Tigray occupy the northern part of the Ethiopian Plateau. This highland, which straddles the Ethiopian-Eritrean border, contains the ancient capitals of the empire: Aksum, Gonder, and Lalibela. For more than half a millennium, however, power lay mainly with the Amhara, who live in the southern part of the plateau in the administrative regions of Gonder, Gojam, and Shewa—the seat of government since 1889. The historic rivalry between these two groups has been reflected most recently in rebellions against "Amhara-dominated" Ethiopia by nationalists in the region of Tigray and by secessionists in Eritrea.

Prone to recurrent drought and famine, the heavily overused Ethiopian Plateau and Eritrean highlands produce the indigenous cereal teff (*Eragrostis abyssinica*), as well as wheat, barley, and, in the drier regions especially, corn (maize) and millet. Cattle and other stock are raised, the land being tilled by ox-drawn plow. In the lower and hotter southern regions of Ethiopia, the false banana, known locally as ensete (*Ensete ventricosum*), is the main crop, and coffee—which is indigenous to Ethiopia and may be named for a local tribe, the Kafa—is produced as a cash crop. There, for the most part, the hand hoe replaces the ox-drawn plow in cultivation. This ensete-growing region is the home of the Gurage (a Semitic-speaking but partly Cushitic people), of the Cushitic Sidamo-speaking peoples, and, to the southwest, of a few other, more distantly connected peoples, whose linguistic affiliation remains a matter of controversy.



Peoples and language areas of the Horn of Africa.

By far the most important group among the Cushitic people is the Oromo, who form the largest ethnic unit in northeastern Africa. They occupy most of the southern provinces of Ethiopia, with the related Somali on their eastern and southern flanks, and seem destined to play an increasingly significant role in the political development of Ethiopia. Their traditional pastoral nomadism is best preserved today among the Boran Oromo, who live in the hot, dry lowlands of southern Ethiopia and northern Kenya. It is from this region that the many different subdivisions of the expanding Oromo nation began their invasion of Ethiopia in the 16th century, sweeping relentlessly in wave after wave into the Christian highlands, where the embattled Amhara and Tigray were unable to check their advance. Those Oromo who moved into the rich central highlands, such as the Macha and Tulama, abandoned their nomadic economy and became sedentary cultivators; others, such as the Arusi and Gudji, in the less-favoured areas sought to combine both modes of livelihood. Many became Christians, adopting Amhara culture; others embraced Islām, although this was not necessarily incompatible with adopting other aspects of Amhara culture.

The inability of the Christians to withstand the Oromo invaders (over whom, however, they later reestablished their ascendancy and whom they finally incorporated as subjects in the empire) shows the extent to which Ethiopian fortunes had been reduced by the ceaseless wars of the period with the surrounding Muslim Sidamo and other largely Cushitic sultanates.

Somali

The Cushitic Somali became fervent Muslims and put increasing pressure on the southeastern flank of the Oromo, thus helping to sustain the latter's continued thrust into Ethiopia. After a long period of turmoil, adjustment, and the reemergence of Amhara ascendancy, under the forceful rule (1889–1913) of Menilek II, Ethiopia assumed its modern shape. Despite their crushing defeat at the Battle of Adowa (Adwa) by the Ethiopians in 1896, the Italians were allowed to retain the largely Muslim and partly Cushitic territory of Eritrea, which was joined to Ethiopia after World War II but became an independent state in 1993.

Notwithstanding their strong sense of cultural nationalism, the Somali had not previously formed a single political unit, and they were partitioned among the Ethiopians, Italians, British, and French. The French also acquired the closely related Cushitic-speaking Afar to form their tiny colony around the port of Djibouti. In 1960 the British and Italian parts of the Somali nation became independent and joined to form Somalia, leaving about a quarter of the total Somali population in the neighbouring areas of eastern Ethiopia, northern Kenya, and the minuscule Republic of Djibouti, which the Somali share with the Afar. Formerly known as French Somaliland, this arid land contains mainly nomads or urban workers.

Traditional ethnic and religious rivalries are thus perpetuated today by the coexistence of a state based on Somali identity (but not including the whole nation) and the ancient state of Ethiopia, which, like most of its more recently formed African neighbours, includes within its borders a variety of different peoples and tribes, about one-third of whom are Muslim and many also Cushitic.

Ethos. The worldviews of the Christian and Muslim peoples of the region are uncannily alike, and, even in particular aspects of belief and ritual, they reveal many striking resonances. Both believe strongly in a morally significant afterlife and are thus capable of accepting present misfortune and illness with fatalistic resignation. Both are also equally adept at seeking alternative mystical explanations of distress and of resorting to supernatural agencies to seek redress. Otherworldly fatalism is thus tempered by a healthy pragmatic concern for present well-being. Those Oromo and Sidamo who retain their traditional cosmologies (and few have remained entirely unaffected by Islām or Christianity) are more firmly anchored in the present and entertain few if any hopes of eternal bliss or fears of eternal damnation.

The most obvious contrasts in cultural outlook and ethos follow the division between cultivator and nomad. The Amhara and Tigray farmers of the highlands are sturdy, canny peasants whose ready deference to their social superiors conceals hostility and suspicion. Their strongly individualistic and shrewdly calculating attitudes suit their hierarchical but far from closed status system and kinship organization.

Specialist crafts, such as weaving, leatherworking, and ironworking, are traditionally despised, and their practitioners are associated with the evil eye. Other artisan work, unskilled manual labour, and even trade also are considered degrading. Specialist minority groups—such as the Dorse weavers or the Cushitic Beta Israel (the Falasha, or "Black Jews"), who traditionally do a considerable amount of ironwork and pottery—are thus able to establish ethnic monopolies. Similarly, the traditionally disparaged Gurage have acquired a leading role as manual workers in Addis Ababa, and, until quite recently, trade has tended to be monopolized by Muslims.

The ethos of the nomads reflects their egalitarian social structure. Their assertiveness contrasts strongly with the deferential respect of the Amhara peasantry. Pragmatic individualism is tempered by the wider demands of the kinship group. Intense and violent competition rages over access to the sparse resources of the environment—grass and water—on which life depends. Enmities and alliances tend to be ephemeral and shifting, the definition of friend and foe constantly changing. In this, the much-divided Somali, whose constituent factions (now armed with automatic rifles) are regularly embroiled in savage feuds, contrast with the Oromo, whose component groups place a high value on internal peace and count the killing of one of their own fellows as a sin. Yet all these warrior nomads—whether Somali, Oromo, or Afar—hold a similar heroic view of life, in which prowess in battle and raiding is the essential manly virtue. The weak and vulnerable receive a certain condescending compassion that is associated with the idea that they may possess special (compensating) mystical powers. In a world in which essentially might is right, however, true prestige is accorded only to those who are manifestly strong and successful. (The Amhara military aristocracy holds similar values.)

Warlike nomads

Kinship, descent, and age-sets. Groups based upon descent from a common ancestor play some role in the social organization of all the peoples mentioned. Generally, it

is patrilineal descent (traced through male ancestors on the father's side of the family) that is of most significance in the inheritance of property and status and in group formation. It is weakest among the Christian Amharas, who regard kinship links traced through either women or men as equally binding. Traditionally, this bilateral kinship system was employed to build up loosely defined clusters of kin each associated with a particular parish or part of a parish. The church-centred local community formed the primary unit in the Amhara administrative system, consisting of a series of scattered hamlets rather than a clearly defined village, and rights to land rested within exogamous kin groups. After the rise of the socialist regime in 1974, land reforms abolished these traditional rights. Control of the land was allocated to local peasant associations (called *kebelles*), which, in the northern Amhara regions, were often chaired by priests.

Among the other mainly Cushitic-speaking peoples (including the Semitic-speaking Gurage), descent is more strictly patrilineal, and conventional kinship groups such as patrilineages and clans occur at various orders of social grouping. Where sedentary cultivation is practiced, as among the central and northern Oromo, the Gurage, and the Sidamo, there is a tendency for particular clans, or their constituent lineages, to be associated with particular localities. Communities may contain the members of several separate descent groups, but one of these is identified with a given locality.

Clans and age-sets

The extent of clan and lineage development and ramification is largely a function of the size of the tribal units involved. The Oromo, for instance, comprise at least eight major tribes, ranging from the most traditional and largely pastoral Gudji and Boran in the south to the strongly Amhara-influenced, cultivating Tulama and Macha around Addis Ababa. In the large units, kinship is only an ancillary principle of association, supplementing more important ties based on shared membership of a generation class, or age-set. According to the so-called *gada* system, all the Oromo male children of the same generation formed an indissoluble fraternity; and, as members of this fraternity, they moved through the various stages of life and positions open to them. The age-sets held in turn the statuses of bachelor-warriors and later of married elders, each set occupying a given grade for a period of approximately eight years. Each generation eventually supplied the lawgivers and leaders of a given Oromo tribe and then retired to make way for its successors.

This form of government was essentially democratic and republican since there was a constant rotation of office-holders and each age-set elected its own leaders who, when the time came, would rule the tribe as a whole. The traditional political system was altered radically, however, as the Oromo expanded northward and many groups changed their location and economy. Political changes also were influenced by the larger Amhara centralized system and by the adoption of either Islām or Christianity, which were often invoked to legitimize new structures of authority.

The *gada* organization provided the strong sense of cohesion that even large nomadic groups such as the Boran were able to achieve. Age-set organization and descent are also significant principles in the local organization of the Sidamo people. But it is among the Afar and certainly the Somali that descent becomes the most significant principle of social and political allegiance. Ties based on common residence in a given area count for less among the northern pastoral Somali than is true of any other group in northeast Africa, and patrilineal kinship is nowhere more important or more heavily utilized in group formation. Patrilineal descent, given specific range and content by contractual treaties, provides the key to the traditional Somali political and legal system. Such treaties result in the formation of distinct politico-legal units, containing a few thousand male kin (and their dependents) who have agreed to meet all liabilities in concert. On this basis, if the parties involved in certain deaths and injuries wish to avoid feuding, they can collectively adjudicate their differences through a system of mutual compensations that aim at a kind of balance of payments. So while lineages of the nomads are not identified with any locality, whenever the need arises scattered kinsmen rally together to attack their foes or defend their interests.

Settlement and livelihood. Village settlements are not found among the Amhara or among those who have been strongly influenced by their culture and way of life. The basic settlement unit in the rural areas is the nuclear or extended family (that is, the husband-and-wife family or its extension to kinfolk, respectively) living in a few circular mud-and-wattle houses. Formerly, the typical parish contained a core of some 20 to 30 household heads descended from a common ancestor associated with the parish and holding landrights in it. This traditional pattern of largely autonomous settlements was radically changed by the socialist government. After 1974, the chairmen of local *kebelles* allocated land to members of the community, and they also selected people for military service, forced labour on state farms, or resettlement elsewhere. To break down the isolation of the peasants and bring them under the control of the central government, a villagization scheme was introduced in 1985. By the end of 1987, eight million people had been regrouped into separate village settlements, each containing up to 500 households. Larger settlements, with thousands of residents from different parts of Ethiopia, were created in an agricultural resettlement project intended to provide arable land and relief from famine.

The Amhara pattern of dispersed settlement is replicated fairly closely among the ensete-growing Sidamo as well as among most of the settled, cultivating Oromo. The Cushitic-speaking Konso with their clearly defined and traditionally fortified villages and the southern Somali with similarly distinct settlements are both unusual. Southern Somali villages are based upon communal water ponds to which access is strictly controlled by membership in the local community and by participation in its blood-compensation arrangements. Among all these groups, land is not traditionally transferable except to other members of the group or to those who join it as clients. Its use entails social and politico-legal obligations, and, when it is abandoned, it reverts traditionally to the local community.

Among the Cushitic pastoralists, settlement patterns are naturally more fluid and flexible. The Boran, who are less mobile and far-ranging than the Somali in their movements, have generally separate grazing encampments for each type of livestock. The Boran rank their animals in the following order: lactating cows, dry cows, lactating camels, dry camels, and sheep and goats. The most senior brother in an extended family herds the first category of stock in the grazing regions best suited to it, and other brothers look after the other animals in descending order of seniority and prestige.

Seasonal movement of nomadic herds

The pastoral Somali nomads, on the other hand, have basically only two types of herding unit. The first consists of the camels, which in the dry seasons can go without water for up to 20 days or more. These are in the charge of young unmarried men and, in the dry seasons particularly, seek good grazing, sometimes hundreds of miles from the wells to which other stock—sheep and goats, cattle and milk camels—are compelled to cling closely. These latter are herded by the family unit, consisting of a man and his wife or wives and their unmarried daughters and young sons (boys over the age of seven are out with the grazing camels learning the techniques of camel management). The family moves from pasture to pasture carrying its readily transportable tents and other equipment on burden camels, which are not, however, ridden. Pasture is not owned, and rights to wells are asserted with an intensity that increases in direct proportion to the scarcity of water and the energy expended in utilizing it. In the wet seasons, when lush pasture regions become centres of intensive grazing and settlement, the two herding units move closer together, and social life becomes more expansive and relaxed. With milk and meat in abundance, this is the time for feasts and collective rituals, the season of marriage negotiation and weddings.

Except among the Christians, all these peoples practice polygyny in one form or another, each wife and her children usually forming a separate domestic and economic unit. Marriage payments, largely in livestock among the

pastoralists, are probably highest in the case of the pastoral Somali. Among these Somali, however, a bride also brings a considerable dowry in the form of a flock of sheep and goats to provide milk for the children whom she is expected to bear her husband.

Finally, a striking feature of Ethiopian economics is the complex and overlapping system of regional markets held in a given centre on a particular day of the week, like the pattern that still obtains in parts of Europe. Saturday is the most popular day. Although such large centres as Gonder or Addis Ababa have daily markets, the weekly market is usually much bigger and has its own distinctive festive atmosphere.

Religion. The Cushitic tradition, traces of which occur even among people as long and deeply Islāmized as the Somali, seems best preserved today (in at least one of its original or early forms) among the Boran. Here Waqa, the god of sky and earth and the creator and sustainer of life, is worshiped in prayer and sacrifice as the guardian of social morality and as the source of all things, good and bad. Waqa's special agents on earth are the sacred dynasties, or lineages, of priests (*kallus*), who still live among the Boran and to whom all the Oromo in ancient times used to send emissaries on pilgrimage. The pilgrims came to receive the blessing of the *kallu* priests, or "anointing fathers," who thus made sacred the whole traditional Oromo social system. Today, among the Macha and other Oromo who now live in the Ethiopian highlands, these traditional national priests have been replaced by new spirit-possessed charismatic leaders (also called *kallus*) who express the ethnic identity of their tribesmen in the context of the Christian Amhara-dominated Ethiopian state.

The Ethiopian Orthodox Church

The Ethiopian Orthodox Church maintains the monophysitic doctrine that Christ has a single nature into which his divine and human sides are assumed. It follows the Alexandrian rite, its liturgy being celebrated and recorded in the ancient Ethiopian language Ge'ez (from which Amharic is derived). It is led by the *abuna,* an Ethiopian priest who before 1948 was appointed by the Coptic patriarch in Alexandria but since has been appointed locally. The *abuna* presides over a church that, with its numerous places of worship, its richly endowed monasteries, and its ample priesthood, held perhaps one-fifth of Ethiopia's arable land before the revolution. Its all-pervasive character is such that one of every five male Christians is estimated to be in orders, and priests are expected to be married, only monks and nuns being celibate. Unordained, but not necessarily unlearned, ritual experts called *debtaras* play a crucial role in dispensing mystically efficacious cures. There is a vast hierarchy of saints and angels, chief among them being the Virgin Mary, St. Gabriel, St. Michael, St. George (patron saint of Ethiopia), and the local saints Tekle Haimanot and Gabra Manfas Keddus. On the darker side, a complementary host of demons and evil spirits, many connected with a form of witchcraft (*buda*) and able to possess people and cause illness and even death, are widely feared. Though officially discouraged under the socialist regime, the protective cult of the saints is still vast and all-embracing. Every Christian has a special relationship with several saints, and the observance of saints' fasts and feasts bulks large in the Christian calendar. Spirits of every origin and provenance are accepted within the Christian cosmology, where they are naturalized in the continuous process of cultural exchange between the dominant and subject peoples. Thus, for instance, the Oromo fertility spirit Atete is readily assimilated to the Virgin Mary, and vice versa.

Exactly the same pattern is repeated on the Muslim side, where the cult of saints is equally well developed and the Islāmic cosmology coincides to a remarkable degree with that of the Amhara Christians. Thus, among the Somali, who posthumously canonize their own lineage ancestors, saints are petitioned to remedy every distress and anxiety and are venerated as essential mediators between man and the Prophet Muḥammad and God. Again, the process of Islāmization closely parallels that of Christianization: in the case of the Arusi Oromo, for instance, the Prophet himself and numerous other Muslim saints are assimilated to traditional spirits and ultimately to Waqa.

If the great traditions of Christianity and Islām generously open their arms to assimilate the many local cultures of the region, many elements from the local cultures in turn find their way, by the back door as it were, into the worldview of the two major religions. This is very clearly seen in the mystery spirit-possession cults, which attract women and certain underprivileged categories of men particularly and which have a strongly "underground" character. Christians are especially susceptible to harassment by Muslim and pagan spirits, just as Muslims are equally open to attack by Christian demons or pagan spirits. Indeed, one of the salient features of religion in this part of Africa is the emphasis placed on spirit possession and the evil eye as explanations of misfortune that elsewhere would be ascribed to witchcraft or sorcery. The other striking feature deserving notice is the stress placed on food taboos and other commensal restrictions that are applied with particular stringency to maintain social distance from hunting and low-status craft groups. The despised and rejected community, on the other hand, may entertain similar attitudes toward those who consider themselves their superiors. Thus, just as other Ethiopians traditionally look down on the religion of the Jewish Falasha and on the ironwork and pottery trades that they follow, the Jewish Falasha themselves seek to remain apart in order to preserve their own ritual purity. Those who have close contact with, or live among, non-Jews are treated with disdain.

Fear of spirits and demons

The presence for centuries of three world religions in the region, each with its own literate tradition, has preserved a more obvious and tangible literary heritage than in most other parts of Africa south of the Sahara, but the bulk of this literature remains largely untranslated and unknown to the outside world. More accessible are the splendid monuments of the Christian past: the celebrated rock-hewn churches of Lalibela, which were largely constructed during the reign of the 12th-century emperor after whom the city is named; the glorious castles and churches of Gonder with their famous, magnificently decorated ceilings; and, beyond this tradition, the older Aksumite antiquities. Islām, too, has left comparable memorials in some of the earliest mosques and tombs in such ancient cities as Harer, Seylac, and Mogadishu but, for religious reasons, has left no illustrations comparable to those adorning Ethiopian manuscripts and church walls. Outside these literate traditions, there exists a less well explored heritage of oral literature, in both prose and poetry. (I.M.L.)

History

EAST AFRICA

The coast until 1856. The earliest written accounts of the East African coast occur in the *Periplus Maris Erythraei*—apparently written by a Greek merchant living in Egypt in the second half of the 1st century AD—and in Ptolemy's *Guide to Geography,* the East African section of which, in its extant form, probably represents a compilation of geographic knowledge available at Byzantium in about 400. The *Periplus* describes in some detail the shore of what was to become northern Somalia. Ships sailed from there to western India to bring back cotton cloth, grain, oil, sugar, and ghee, while others moved down the Red Sea to the East African coast bringing cloaks, tunics, copper, and tin. Aromatic gums, tortoiseshell, ivory, and slaves were traded in return.

Early trade with Arabia

Azania. Because of offshore islands, better landing places, and wetter climate, Arab traders from about 700 seem to have preferred the East African coast to the south of modern Somalia. They sailed there with the northeast monsoon, returning home in the summer with the southwest. They dubbed the part of the coast to which they sailed Azania, or the Land of Zanj—by which they meant the land of the blacks and by which they knew it until the 10th century. South of Sarapion, Nikon, the Pyralaae Islands, and the island of Diorux (about whose precise location only speculation seems possible), the chief town was Rhapta, which may lie buried in the Rufiji delta of present-day Tanzania. Here the situation differed somewhat from that in the north, and, though tortoiseshell and rhinoceros horn were exported from there—as were

quantities of ivory and coconut oil—no mention is made of slaves. Rhapta's main imports were metal weapons and iron tools—suggesting that iron smelting was not yet known. Mafia Island, which lies out to sea here, could perhaps be Menouthias, the only island named in both the *Periplus* and the *Guide*, although this could also be either Pemba or Zanzibar (perhaps there has been a conflation of all three in the one name).

There is little information concerning the period until the 8th century. Greek and Roman coins have been found, and there are some accounts of overseas migrations to the coast. No settlements from this period have been found.

A new period opened, it seems, in the 9th century. The first identifiable building sites are dated from this time, and, according to Arab geographers, the East African coast was then generally thought of as being divided into four: (1) Berber, which ran down the Somalian coast to the Shabeelle River, (2) Zanj proper, (3) the land of Sofala in present-day Mozambique, whence gold was beginning to be shipped by about the 10th century, and (4) a vaguely described land of Waq waq, beyond. The only island that is mentioned is Qanbalu, which appears to have been what is now Tanzania's Pemba Island. Though there is some suggestion that in the 10th century the Muslims had not yet begun to move farther south than Somalia, on Qanbalu they soon became rulers of a pagan population, whose language they adopted. Moreover, at Zanzibar an extant Kūfic inscription (the only one) recording the construction of a mosque by Sheikh as-Sayyid Abū 'Imrān Mūsā ibn al-Ḥasan ibn Muḥammad in 1107 confirms that by this time substantial Muslim settlements had been established.

The main coastal settlements were situated on islands, largely, no doubt, because of the greater security these provided against attacks from the mainland; and their populations seem mostly to have been made up from migrants from the Persian Gulf—some from the great port of Sīrāf, others from near Bahrain—though conceivably some too came from Daybul, at the mouth of the Indus River, in northwestern India. They exported ivory (some of it went as far as China) and also tortoiseshell, ambergris, and leopard skins. Such trade goods as they obtained from the interior were apparently bought by barter at the coast.

Kilwa

Ruins at Kilwa, on the southern Tanzanian coast, probably date from the 9th or perhaps from the 8th century. They have revealed an extensive pre-Muslim settlement standing on the edge of what was the finest harbour on the coast. Though there is little evidence to suggest that its inhabitants had any buildings to begin with, wattle-and-daub dwellings appeared in due course, and by the 10th century short lengths of coral masonry wall were being built. The inhabitants, whose main local currency was cowrie shells, traded with the peoples of the Persian Gulf and, by the early 11th century, had first come under Muslim influence. By 1300, like the inhabitants of neighbouring Mafia, they were living in Muslim towns, the rulers of which were Shī'ites. Although no houses were being built of coral, stone mosques were being constructed.

External trade was increasing: glass beads were being imported from India, and porcelains, transshipped either in India or in the Persian Gulf, were arriving from China. There appears also to have been a rather extensive trade with the island of Madagascar.

The most important site of this period yet to have been found is at Manda, near Lamu, on the Kenyan coast. Apparently established in the 9th century, it is distinguished for its seawalls of coral blocks, each of which weighs up to a ton. Though the majority of its houses were of wattle and daub, there were also some of stone. Trade, which seems to have been by barter, was considerable, with the main export probably of ivory. Manda had close trading connections with the Persian Gulf—with Sīrāf in particular. It imported large quantities of Islāmic pottery and, in the 9th and 10th centuries, Chinese porcelain. There is evidence of a considerable iron-smelting industry at Manda and of a lesser one at Kilwa.

The Shirazi migration. For much of the 13th century the most important coastal town was Mogadishu, a mercantile city on the Somalian coast to which new migrants came from the Persian Gulf and southern Arabia. Of these, the most important were called Shirazi, who, in the second half of the 12th century, had migrated southward to the Lamu islands, to Pemba, to Mafia, to the Comoro Islands, and to Kilwa, where by the end of the 12th century they had established a dynasty. Whether they were actually Persian in origin is somewhat doubtful. Though much troubled by wars, by the latter part of the 13th century they had made Kilwa second in importance only to Mogadishu. When the Kilwa throne was seized by Abū al-Mawāhib, major new developments ensued. Kilwa captured Mogadishu's erstwhile monopoly of the gold trade with Sofala and exchanged cloth—much of it made at Kilwa—and glass beads for gold; and with the great wealth that resulted new pottery styles were developed, a marked increase in the import of Chinese porcelain occurred, and stone houses, which had hitherto been rare, became common. The great palace of Husuni Kubwa, with well over 100 rooms, was built at this time and had the distinction of being the largest single building in all sub-Saharan Africa. Husuni Ndogo, with its massive enclosure walls, was probably built at this time, too, as were the extensions to the great mosque at Kilwa. The architectural inspiration of these buildings was Arab, their craftsmanship was of a high standard, and the grammar of their inscriptions was impeccable. Kilwa declined in the late 14th century and revived in the first half of the 15th, but then—partly because of internal dynastic conflict but also partly because of diminishing profits from the gold trade—it declined again thereafter.

Prosperity in the 15th century

Elsewhere, especially on the Kenyan coastline, the first half of the 15th century seems to have been a period of much prosperity. Whether at Gede (south of Malindi) or at Songo Mnara (south of Kilwa), architectural styles were relatively uniform. Single-story stone houses, mostly of coral, were common. Each coastal settlement had a stone mosque, which, typically, centred upon a roofed rectangular hall divided by masonry pillars. Chinese imports arrived in ever larger quantities, and there are signs that eating bowls were beginning to come into more common use. Mombasa became a very substantial town, as did Pate, in the Lamu islands. The ruling classes of these towns were Muslims of mixed Arab and African descent who were mostly involved in trade; beneath them were African labourers who were often slaves and a transient Arab population. The impetus in this society was Islāmic rather than African. It was bound by sea to the distant Islāmic world, whence immigrants still arrived to settle on the East African coast, to intermarry with local people, and to adopt the Swahili language. The impact of these settlements was limited, while their influence upon the East African interior was nonexistent.

During the 15th century, Shirazi families continued to rule in Malindi, Mombasa, and Kilwa and at many lesser places along the coast. They also dominated Zanzibar and Pemba. The Nabahani, who were of Omani origin, ruled at Pate and were well-represented in Pemba as well. Coastal society derived a certain unity by its participation in a single trading network, by a common adherence to Islām, and by the ties of blood and marriage among its leading families. Politically, however, its city-states were largely independent, acknowledging no foreign control, and their limited resources confined their political activities to East Africa and to a variety of local rivalries—Zanzibar and Pemba, for example, appear frequently to have been divided between several local rulers. Mombasa occupied the premier position on this part of the coast, although its control over the area immediately to the north was disputed by its main rival, Malindi. Close connections seem to have existed between Mombasa and a number of places to the south. Its Shirazi rulers were able to mobilize military support from some of the inland peoples, and as a result of the place it had won in the trade of the northwestern Indian Ocean they had turned Mombasa into a prosperous town. Its population of about 10,000 compared with only 4,000 at Kilwa.

The Portuguese invasion. This was the situation on the East African coast when Portuguese ships under Vasco da Gama arrived in 1498. The manifestly superior military and naval technology of the Portuguese and the greater

unity of their command enabled them, in the years that lay ahead, to mount assaults upon the ill-defended city-states. As early as 1502 the sheikh at Kilwa was obliged to agree to a tribute to the Portuguese, as the ruler of Zanzibar was later. Shortly afterward the Portuguese sacked both Kilwa and Mombasa and forced Lamu and Pate to submit. Within eight years of their arrival they had managed to dominate the coast and the trade routes that led from there to India.

Ejection of the Shirazi

The Portuguese became skilled at playing one small state against another, but their global enterprise was such that they did not immediately impose direct rule. This changed toward the end of the 16th century, however, when Turkish expeditions descending the northern coast with promises of assistance against the Portuguese encouraged the coast north of Pemba to revolt. This prompted the dispatch of Portuguese fleets from Goa, one of which, in 1589, sacked Mombasa and placed that city much more firmly under Portuguese control. This was helped by the death of Mombasa's last Shirazi ruler, Shah ibn Mishhan, who, in leaving no clear successor, gave the Portuguese the opportunity to install Sheikh Aḥmad of Malindi in his place. In 1593, with an architect from Italy in charge and with masons from India to assist them, the Portuguese set about building their great Fort Jesus at Mombasa. In the following year it was occupied by a garrison of 100 men.

With Mombasa's downfall, the major hindrance to Portuguese power on the East African coast was overthrown. They installed garrisons elsewhere than at Mombasa and brought about the downfall of a number of Shirazi dynasties, and, although they did not exercise day-to-day control over local rulers, they did make them dependent on them for their position. (Local rulers were in particular required to pay regular tribute to the Portuguese king on pain of dethronement and even of death.)

Portugal's chief interests were not imperial but economic. With Mombasa in their grip, they controlled the commercial system of the western Indian Ocean. Customs houses were opened at Mombasa and Pate, and ironware, weapons, beads, jewelry, cotton, and silks were imported. The main exports were ivory, gold, ambergris, and coral. There was a flourishing local trade in timber, pitch, rice, and cereals but few signs of any considerable traffic in slaves. Individual Portuguese traders often developed excellent relations with Swahilis in the coastal cities.

Though the Portuguese managed to ride out local rebellions into the 17th century, their authority over a much wider area was undermined by the rise of new powers on the Persian Gulf. Portugal lost Hormuz to the Persians in 1622 and Muscat to the imam of Oman in 1650. Two years later the Omanis launched their first major intervention into East Africa's affairs when in response to a Mombasan appeal the imam sent ships to Pate and Zanzibar and killed their Portuguese inhabitants. As a consequence, Pate became the centre of East Africa's resistance to Portuguese rule. The Portuguese responded in an equally bloody manner, but eventually, in 1696, in alliance with Pate, the imam of Oman sailed to East Africa with a fleet of more than 3,000 men to lay siege to Mombasa. Although Fort Jesus was reinforced, the great Portuguese stronghold finally fell to Sayf ibn Sulṭān in December 1698. A few years later Zanzibar, the last of Portugal's allies in Eastern Africa, also fell to the imam.

The Omani ascendancy. There ensued, after the Omani victory, a century during which, despite a succession of Omani incursions, the East African coast remained very largely free from the dominance of any outside power. Oman itself suffered an invasion by the Persians and was long distracted by civil conflict. Its originally successful Yaʿrubid dynasty lost prestige as a consequence, fell from power, and was then superseded by the Āl Bū Saʿīdīs, who very soon found themselves preoccupied by conflicts at home. Moves against them also originated along the East African coast.

The Āl Bū Saʿīdī dynasty

In 1727 Pate joined with the Portuguese to expel the Omanis, especially from Mombasa, where in 1728–29 Portuguese authority was momentarily restored. But the Mombasans wanted as little to be controlled by Portugal as by Muscat and soon evicted the Portuguese once again. Thereafter, Kilwa, Zanzibar, Lamu, and Pate largely kept themselves free from both Omani and Portuguese control. Distracted though it was by protracted internecine quarrels, Pate was preeminent in the Lamu archipelago and, like all the other coastal towns, was ambitious to preserve its independence.

Even so, Mombasa, in quite new circumstances, in the 18th century reached the apogee of its power as an independent city-state. The architects of this achievement were the Mazrui, an Omani clan who had provided some of the imam's governors to Mombasa but who, because they were opposed to the Āl Bū Saʿīdīs, did not long persist in their allegiance to Muscat. They owed their authority in Mombasa itself to an ability to hold the balance between the rival factions in the Swahili population and also to their ability peacefully to overcome all but one of their dynastic successions. In 1746 a Mazrui notable, ʿAlī ibn Uthman al-Mazrui, overthrew an Omani force that had murdered his brother. Soon after he seized Pemba and, but for a family quarrel, might have won Zanzibar; his successor, Masʿūd ibn Nāṣir, initiated a pattern of cooperation with Pate, maintained close links with inland Nyika peoples, and established Mazrui dominance from the Pangani River to Malindi.

Both Mombasa and Pate were disastrously defeated by Lamu in the battle of Shela, *c.* 1810. Pate's preeminence in the Lamu islands was destroyed, Mombasa's authority on the coast was diminished, and the way was open to Muscat's great intrusion into East African affairs. Lamu appealed to Oman for a garrison to assist it, to which Sayyid Saʿīd of Muscat very soon responded.

The Āl Bū Saʿīdīs, who had captured Kilwa in 1785, maintained their principal footing upon the coast in Zanzibar, which had long held to its association with them. Thanks to the city's growing success, from the end of the 18th century onward, in turning itself into the main entrepôt for the trade in the area south of Mombasa, Zanzibar soon rivaled Mombasa as the focal point for the whole coastline. As such, it was both developed and used by Sayyid Saʿīd ibn Sulṭān of Oman as the base for his growing ambitions. Having won the succession to Muscat after an internecine struggle following his father's death in 1804, Saʿīd spent much of the next two decades establishing his authority there. (In this he was assisted by the British, who were much concerned to safeguard their route to India, which ran close to Muscat on its way past the Persian Gulf.) Then, in 1822, he wrested Pemba from Mazrui control and by 1824 had installed a Muscat garrison in Pate as well, thus bringing to an end the previous influence that the Mazrui had exercised.

The rise of Zanzibar

Sensing the increasing threat from Muscat, the Mazrui appealed to the British for assistance. Though their application was formally denied, a British naval officer, Captain W.F. Owen, on his own initiative raised a British flag of protection over Mombasa in 1824. Since the British had no desire formally to extend their authority to East Africa at this time, let alone to break with their ally Saʿīd, it was hauled down in 1826. This gave Saʿīd his opportunity, and in 1828, 1829, and 1833 he mounted assaults upon Mombasa. But it was only when he successfully intervened in a dynastic dispute among the Mazrui, which followed on the death of a *liwali* in 1835, that he was able in 1837 to fasten his control over Mombasa and to topple the Mazrui from their position. His dominion along the whole coastline thus became assured, and after over a century's interval the East African littoral once more found itself dominated by a single outside power. Though this outcome owed much to the inability of the coastal towns to unite against an invader, it owed much as well to the striking personality of Saʿīd himself, to his investment in a navy, to his force of Baluchi soldiers (with which he supplemented his Omani levies), and to the support he received from the British.

It also stemmed from his intimate association with the major economic developments then taking place along the East African coast. These began with a marked growth in the previously marginal slave trade, particularly at first in the Kilwa region, more especially from 1780 to 1810 as a result of French demand for slaves in Mauritius and

Bourbon. This was succeeded by the discovery that cloves could be successfully grown on Zanzibar and by the development of flourishing plantations. British pressure on Sa'īd to end the export of slaves to "Christian" markets came to fruition in 1822, when he reluctantly signed what became known as the Moresby Treaty. In the event, however, it made very little difference, either on the coast or in the interior, since slaves were being required in growing numbers for the plantations on both Zanzibar and Pemba and for export to the Persian Gulf and beyond.

Increasing commercial activity brought Sayyid Sa'īd sufficient wealth to buy ships and pay troops. It also attracted to the East African coast migrant Indians, who became heavily involved in the country's economic expansion; and, together with the Arabs who were beginning to make profits from their clove plantations, Indians helped to finance the new upcountry trading caravans.

Trade with Europeans

The increased economic activity that centred upon the islands of Zanzibar and Pemba served to enhance the importance of the smaller towns that stood on the mainland opposite. It also attracted an influx of European traders, of which the most important were the Americans. They were the first Westerners to conclude a trade agreement with Sa'īd (1833) and the first also to establish a consul at Zanzibar (1837). (Their prime achievement was to capture the cloth trade to East Africa—so that cheap cotton cloth thenceforth came to be known there as Americani.) The British followed with a trade agreement in 1839 and a consul in 1841. The French made similar provisions in 1844, and some Germans from the Hanseatic towns moved in at about the same time. British trade, however, never flourished and in fact died away; but by 1856 America and France were both making purchases in East Africa of more than $500,000 a year, while exports to India, particularly British India, were higher still. Some of the main items of trade, such as ivory, were traditional, but copal, sesame, cloves, cowries, hides, and coconut oil were also important. Because of this increased activity, Sa'īd's economy in due course became less dependent upon the export of slaves, and he therefore showed himself more ready than he might otherwise have been to accept the so-called Hamerton Treaty of 1845, by which the export of slaves to his Arabian dominions was forbidden.

Since by this time the revenues from Sa'īd's East African territories had overtaken those he received from Oman, it is understandable that in 1840 he should have transferred his own capital from Muscat to Zanzibar. At his death in 1856, Zanzibar was firmly established as the East African coast's main centre, from which major new incursions into the interior had begun to radiate extensively.

The interior before the colonial era. *The Stone Age.* The coast was never more than East Africa's fringe. Beyond the harsh *nyika,* or wilderness, which lay immediately inland and was nowhere pierced by a long, navigable river, thornbush country extended to the south, sometimes interspersed with pleasanter plains toward the centre, while to the north cooler forested highlands ran into harsher country. Westward lay the Great Rift Valley and, beyond, the regions of the great lakes whence the Nile ran northward through its usually impassable marshes.

Since there are no written records antedating the last century or so for this region, its history has to be deduced from often uncertain linguistic, cultural, and anthropological evidence; from oral traditions—where they are available, which at best is only for recent centuries; and from archaeological findings. Since investigations and analyses are still at a very early stage and since the first hypotheses have proved vulnerable to criticism, the statements that follow must be only tentative. Furthermore, all accounts of tribal migration must allow for innumerable short-run moves and may refer only to small—if important—minorities. They must also take account of probable interactions with other peoples en route and often, indeed, of extensive absorption. Above all, care must be exercised over anachronistic concepts of "tribe." Moreover, bolder categories such as Bantu are strictly only linguistic and must be treated with caution.

Two features of the pre-19th-century period may be stressed: first, although it seems to have been in this part of Africa that man first developed, in the three or four most recent millennia the key innovations in man's evolution seem to have occurred elsewhere; second, the extensive agricultural revolution in East Africa, which took place during this time, had the vital consequence that sizable populations grew up in areas of adequate rainfall, which could not be easily brushed aside by subsequent alien invaders.

Beginning of agriculture

During the earlier stages of the Stone Age down to about 50,000 BC, hand-ax industries were established in the Rift Valley areas of Kenya and of Tanzania (especially at Olduvai Gorge) and along the Kagera River in Uganda. During the Mesolithic period (thence to *c.* 10,000 BC), new stone-tool-making techniques evolved, and the use of fire was mastered. Spreading to other parts of East Africa, in the Neolithic period man clustered into specialized hunting and gathering communities from which may have developed some still-existing ways of life. The largest number of relevant sites is close to the homeland of the Hadzapi—the last contemporary hunters and gatherers—and to that of the Sandawe, who are physically and linguistically akin to the San (or Bushmen) of southern Africa. Remnants of other hunting and gathering communities—such as the Pygmies of western Uganda—or at least the memory of them, are found in many places. Latterly, they often lived in precisely those highland regions where agriculture and animal domestication in East Africa first occurred.

Food production and the keeping of cattle seem to have begun in the highland and Rift Valley regions of Kenya and of northern Tanzania in the 1st millennium BC and to have derived from Caucasoid peoples who were probably southern Cushites from Ethiopia. Some traces of these interlopers remain among, for example, the Iraqw of Tanzania, and it may be that the age-old systems of irrigation found throughout this region owe their origins to this period as well. Agriculture preceded the smelting of iron in these areas, and hunting and gathering continued to be important for the domestic economy. It looks as if in due course southern Cushites spread deep into what is now southern Tanzania, but, so far as has been ascertained, food production did not develop in the period BC elsewhere in Tanzania, nor in what is now Uganda.

The spread of ironworking and the Bantu migrations. It is still far from clear when and whence iron smelting spread to the East African interior. Certainly there was no swift or complete transfer from stone to iron. At Engaruka, for example, in that same region of the Rift Valley in northern Tanzania, a major Iron Age site, which was both an important and concentrated agricultural settlement using irrigation, seems to have been occupied for over a thousand years. Significantly, its styles of pottery do not seem to have been related to those that became widespread in the 1st millennium AD. It is a reasonable assumption that its inhabitants were Cushitic speakers, but it seems that its major period belongs to the middle of the 2nd millennium AD.

Spread of agriculture, ironworking, and Bantu speakers

The major occurrences of the 1st millennium AD involved the spread of agriculture—more particularly, the cultivation of the banana—to the remaining areas of East Africa. Simultaneously or perhaps previously went the spread of ironworking, and fairly certainly too the diffusion of Bantu languages—except in the core of the Cushitic wedge and to the north of an east–west line through Lake Kyoga. If, as seems probable, proto-Bantu languages had their origins in the eastern interior of West Africa, it does not seem inconceivable that over a lengthy period of time some of its speakers, probably carrying with them a knowledge of grain agriculture and conceivably a knowledge of ironworking, should have diffused along the tributaries of the Congo River to the savanna country south of the Congo forest into what is now the region of Shaba in Zaire. Nor does it seem inconceivable that the banana, originally an Indonesian plant particularly suitable in tropical conditions, should have spread to that same region up the Zambezi valley (certainly the Malayo-Polynesian influences in Madagascar in the 1st millennium AD are well attested in other respects). At all events, the linguistic and archaeological arguments for a fairly rapid eastward and northward expansion during the

1st millennium AD from the Shaba area now have wide acceptance. Bantu languages came to dominate most of this region (many Cushitic speakers in what is now Tanzania seem to have switched over to them or to have been eliminated). More varieties of banana developed in East Africa than anywhere else in the world. Ironworking was soon prevalent, and, where rainfall, soil nutrients, and the absence of the tsetse fly allowed, population growth increased decisively.

The early interlacustrine kingdoms. Sometime before the middle of the 2nd millennium AD, some of the most interesting developments were occurring in the interlacustrine area—*i.e.*, the region bounded by Lakes Victoria, Kyoga, Albert, Edward, and Tanganyika. Vague accounts of rulerships in various parts of this area date from the first half of the 2nd millennium AD, and it is at least possible that they existed—though they may well have been judicial arbitrators or ritual leaders rather than more strictly political figures. Whether they had their origins in roving Cushitic or Nilotic cattle keepers from the north or northeast—as has been variously suggested—is impossible to say, though some such explanation would not be difficult to believe. What seems certain is that around the middle of the present millennium a sudden cultural political climax was marked by a short-lived, though widely acknowledged, dynasty of Chwezi rulers.

Earthworks at Bigo

The Chwezi people are frequently associated with the great earthwork sites at Bigo, Mubende, Munsa, Kibengo, and Bugoma, in western Uganda. That at Mubende seems to have been a religious centre. The largest is at Bigo, where a ditch system, over six and a half miles long, some of it cut out of rock, encloses a large grazing area on a riverbank. It looks as if it comprised both a royal capital and a well-defended cattle enclosure. Its construction must certainly have required a considerable mobilization of labour—which, apart from indicating that it must have been the work of a substantial political power, would support the view that the distinction between cultivators and a pastoral aristocracy, which later became typical of this area, is of very long standing. Radioactive carbon dating suggests Bigo was occupied from the mid-14th to the early 16th century. This correlates with the evidence of oral tradition that around the turn of the 15th century the Chwezi were supplanted in the north by Luo rulers of the Bito clan (who provided the dynasties that ruled in Bunyoro, Koki, Buganda, and parts of Busoga) and that they were superseded to the south by various Hima rulers of the Hinda clan (in Ankole, Buhaya, Busubi, and around to the southeast of Lake Victoria). Under these, and the corresponding Nyiginya dynasty in Rwanda, powerful traditional rulerships among the interlacustrine Bantu persisted after the middle of the 20th century.

Their relatively common experience was reinforced in the aftermath of the Chwezi dynasty by the prevalence among them of a variety of (often commemorative) Chwezi religious movements. In some areas these took the form of spirit-possession cults; in others, pantheons of deities were developed. In various guises—sometimes in support of the existing political order, sometimes against it—they spread into Bunyoro, Buganda, Busoga, Ankole, Buha, Rwanda, Burundi, and even to Nyamwezi country, in what is now Tanzania. So extensive a diffusion of a basically common religious tradition in any other part of the East African interior before the much later arrival of Islām and Christianity was rare indeed.

The chieftainships of the southern savanna. In northwestern Tanzania, dynasties of a pre-Chwezi kind apparently spread from the interlacustrine area during the middle centuries of the present millennium. *Ntemi* (as the office was called) became prevalent among both the Sukuma and the Nyamwezi. They (the *ntemi*) were probably as much ritual leaders as political rulers; certainly they do not seem to have exercised before the 19th century a "state" authority that was characteristic of the later interlacustrine rulers. By about the 16th century there may have been an extension of this style of chieftainship southward into southwestern Tanzania. At all events, the chiefly groups among the Nyamwanga, the Nyika, the Safwa, the Ngonde, the Kinga, the Bena, the Pangwa, the Hehe, and the Sangu have common traditions of origin, and it seems clear that they are to be distinguished from their significantly different, matrilineal neighbours in southern Tanzania, Zambia, and Zaire. There also seem to have been secondary movements of *ntemi*-like institutions in the 18th century to Ugogo, Safwa, Kaguru, Kilimanjaro, and Usambara. At the same time, the development of chieftainships in these other areas of Tanzania may originally have occurred independently of influences from elsewhere.

Shungwaya

Northeastern Bantu. The spread of some Bantu to the northern coast of East Africa during the 1st millennium AD is supported by the memory of a settlement area named Shungwaya situated to the north of the Tana River. Shungwaya appears to have had its heyday as a Bantu settlement area between perhaps the 12th and the 15th centuries, after which it was subjected to a full-scale invasion of Cushitic-speaking Oromo peoples from the Horn of Africa. There is controversy as to whether the ancestors of the present Kamba and Kikuyu of Kenya were from Shungwaya, but it would seem that they probably broke away from there some time before the Oromo onslaught. It has been suggested, indeed, that the Kikuyu spread through their present territories from 1400 to 1800. The old Cushitic wedge checked them from spreading farther westward. This extended, as it would seem to have done for two or more millennia past, over both sides of the Kenyan and northern Tanzanian Rift Valley, but in the middle of the present millennium it was subjected to one of the multiple waves of invading Nilotic peoples—who were partly agriculturists and partly pastoralists—that moved into much of the northern and northwestern parts of East Africa.

The Nilotic migrations. The supersession of the Chwezi by Luo dynasties in the northern interlacustrine region at about the end of the 15th century resulted from the migrations of Nilotic peoples southward—in this instance, it has seemed, from a cradleland in what is now The Sudan.

For some 18 generations or so Bito rulers of Luo origin held sway over the kingdom of Bunyoro-Kitara, to the east of Lake Albert. Though at first their dominion seems to have been widely extended, they began to be rivaled in the 16th and 17th centuries by the rise of Buganda, under its ruler, or kabaka. Working on interior lines and based upon a particularly fertile region, Buganda developed a strength and cohesion that from the 18th century onward was to make it—with Rwanda—one of the two most formidable kingdoms of the region.
